# **A Poisson Regression Examination of the Relationship between Website Traffic and Search Engine Queries**

**By**

**Heather L.R. Tierney\* and Bing Pan**

November 2009

## **Abstract**

A new area of research involves the use of Google data, which has been normalized and scaled to predict economic activity. In this paper, Poisson regressions are used to explore the relationship between the online traffic to a specific website and the search volumes for certain keyword search queries, along with the rankings of that specific website for those queries. Daily and weekly data are used to discuss the effects that normalization, scaling, and aggregation have on the empirical findings, which are frequency-dependent.

**KEYWORDS:** Poisson Regression, Search Engine, Google Insights, Aggregation,

**JEL Classification Codes:** C25, C43, D83

## 1. Introduction

A burgeoning field of research involves using data from Google Insights or Google Trends to predict economic activities (Askatas and Zimmerman 2009, Choi and Varian, 2009a, Choi and Varian, 2009b). The lure of using Google data, which has already been normalized, scaled, and aggregated, is that one has instantaneous access to worldwide internet activity.<sup>1</sup> Studies in other fields that use scaled variables such as in Geographic Information Systems (GIS) and aggregated variables such as in time series econometrics have found that models involving scaling or data aggregation can introduce a loss of information. The loss will be larger with larger scales and greater levels of aggregation (Rossana and Seater 1995, Bian 1997). Furthermore, scaling a variable in regards to range also has the possibility of producing distortions (Pyle 1999). In general, the effect of normalization, scaling, and aggregation in regards to website traffic and search engine queries has not been directly examined, and this paper investigates the potential pitfalls of using such data.

Internet activity has been used to predict economic activity and even possible flu epidemics (Ginsberg, Mohebbi, Patel, Brammer, Smolinski, and Brilliant 2009). In regards to internet activity with respect to economic activity, Azar (2009) finds a negative relationship between oil prices and shocks to Google searches for electric cars in a Bayesian Vector Autoregression (BVAR). Askatas and Zimmermann (2009) observe a strong correlation between certain keywords such as *unemployment office or agency*, *unemployment rate*, *Personnel Consultant*, and *most popular job search engines in German* and the monthly German unemployment rate using Engle and Granger's (1987) error correction model. In a technical paper, Choi and Varian (2009b) state that the out-of-sample fit of U.S. initial unemployment claims is better explained with the inclusion of data from Google Trends in an ARIMA framework. Using daily and weekly data from Google Trends, Choi and Varian (2009a) also look at the relationship of retail sales and automotive sales using a seasonal autoregressive (AR) model, home sales in an AR model, and travel,

---

<sup>1</sup> Google does not use the terms normalizing and scaling interchangeably.

with respect to visitor arrival in Hong Kong, in a fixed effects model in an earlier technical paper.

The purpose of this paper is two-fold. The first purpose is to understand the relationship between website traffic to a given website and keyword search queries as well as the rankings of that specific site for those queries. The understanding and modeling of website traffic could have important implications in terms of the gathering of predictive variables from external business environments, which could help in predicting revenue generation for individual businesses. The second purpose is to investigate the effect that normalized, scaled, and aggregated variables of internet activity have on the empirical results, which has an important bearing on a new frontier of research that involves Google data.

Using daily and weekly data from Google Trends, a Poisson regression model with a conditional exponential mean function is adopted to model the website traffic of the Charleston Area Convention and Visitors Bureau (CACVB) website.<sup>2</sup> Following the reasoning of Michener and Tighe (1992), the Poisson model is used since website traffic is a non-negative integer variable (Cameron and Trivedi 1998). This paper finds that search volumes for certain keyword search queries has a larger impact on website traffic than does the ranking of a website especially with respect to the CACVB website. The most important finding of this paper is that the frequency of Google data used in the regressions can greatly impact the empirical findings in terms of the magnitude of the estimated coefficients and even possibly with respect to the statistical significance of an estimated coefficient.

The structure of this paper is as follows: Section 2 presents the theoretical model, Section 3 discusses the empirical findings, and Section 4 concludes.

## **2. Theoretical Model**

The data used as the regressands are various forms of website traffic to the CACVB website, which necessitates the use of a generalized linear model (GLM).

---

<sup>2</sup> The web address of the CACVB website is as follows: [www.charlestoncvb.com](http://www.charlestoncvb.com).

The regressand for each of the regressions is a count variable, which only takes on non-negative integer values  $\{y_t \in \mathbb{Z}^+ : y_t \geq 0\}$  with  $t = \{1, \dots, T\}$  (Cameron and Trivedi 1998).

The particular GLM model used in this paper is the Poisson maximum likelihood estimator (MLE), an exponential conditional mean model,  $E[y_t | \mathbf{x}_t]$ , which is of the following form:

$$y_t = m(\mathbf{x}_t, \boldsymbol{\beta}) = \exp(\mathbf{x}'_t \boldsymbol{\beta}) = \exp(\beta_0 + \beta_1 x_{1t} + \dots + \beta_k x_{kt}) \quad (1)$$

where  $y_t$  is the regressand and  $\mathbf{x}_t$  is the regressor matrix with  $t = \{1, \dots, T\}$  (Cameron and Trivedi 1998).

For the purposes of estimation, the Poisson quasi-maximum likelihood estimator (QMLE) is used since it relaxes the assumption that the conditional variance and conditional mean are the same, and hence, the model is of the following form:

$$y_t = \exp(\mathbf{x}'_t \boldsymbol{\beta}) + \varepsilon_t = \exp(\beta_0 + \beta_1 x_{1t} + \dots + \beta_k x_{kt}) + \varepsilon_t \quad (2)$$

where the error term is  $\varepsilon_t \sim N(0, \sigma^2)$  (Wooldridge 1999).

In the estimation of Equation (2), overdispersion is found to be present, which means that  $\sigma^2 > 1$  and along with the Poisson GLM variance assumption, the conditional variance is permitted to be greater than the conditional mean:

$$\text{var}(y | \mathbf{x}) = \sigma^2 m(\mathbf{x}, \boldsymbol{\beta}). \quad (3)$$

A consistent estimator of  $\sigma^2$  involves the use of the standardized or weighted error terms, which are often referred to as the Pearson error terms, and are needed for the standard errors of the regression parameters. The  $t^{\text{th}}$  iteration of Equation (2) is:

$$\varepsilon_t = y_t - m(\mathbf{x}_t, \boldsymbol{\beta}), \quad (4)$$

Using the error terms from all  $t$ -iterations of Equation (4), the consistent estimator of  $\sigma^2$  is the expectation of the sum of squared weighted error terms, which is of the following form:

$$\sigma^2 = E\left(\frac{\varepsilon_t^2}{m_t}\right) \quad (5)$$

(Wooldridge, 2002).

The benefits of using the Poisson QMLE are that the parameters of the Poisson QMLE are consistent even if the underlying distribution is incorrectly specified and is relatively efficient with robust standard errors, which take into account heteroskedasticity. In addition, the Poisson QMLEs are asymptotically normal (Cameron and Trivedi 1998, Wooldridge 1999).<sup>3</sup>

The interpretation of the regression parameters are not as straight forward as a linear regression model since the Poisson QMLE involves the exponential mean function. The marginal effect of  $x_j$  on  $E[y_t | \mathbf{x}_t]$  is interpreted as the proportional change of  $E[y_t | \mathbf{x}_t]$  by the amount,  $\beta_j$ , i.e.

$$\frac{\partial E[y_t | \mathbf{x}_t]}{\partial x_{jt}} = \exp(\beta_0 + \beta_1 x_{1t} + \dots + \beta_k x_{kt}) \times \beta_j = E[y_t | \mathbf{x}_t] \times \beta_j \quad (6)$$

where  $j = \{1, \dots, k\}$  (Cameron and Trivedi 1998). Furthermore, if  $x_j$  is the log of a scale variable, then the regression coefficient,  $\beta_j$  can be interpreted using one particular definition of elasticity, which is also as a proportional change in  $E[y_t | \mathbf{x}_t]$  (Michener and Tighe 1992, Cameron and Trivedi 1998).

Another way of interpreting the Poisson QMLE involves taking the log of Equation (1), which is:

$$\log(y_t) = \log(m(\mathbf{x}_t, \beta)) = \mathbf{x}_t' \beta = \beta_0 + \beta_1 x_{1t} + \dots + \beta_k x_{kt}. \quad (7)$$

Suppose  $x_j$  is a log variable, then if the regressor is not a log variable, then  $\beta_j$  can be interpreted as a semi-elasticity, meaning that a one unit change in  $x_j$  will change  $E[y | \mathbf{x}]$  by  $100\beta_j$ . If the regressor is a log variable, then  $\beta_j$  can be interpreted as an

---

<sup>3</sup> An alternative model to the Poisson QMLE is the two-step negative binomial QMLE, which does not produce robust findings, and hence is not used in this paper (Wooldridge, 1999).

elasticity, meaning that  $\beta_j$  is the percent change in  $E[y|\mathbf{x}]$  due to a percentage change in  $x_j$  (Cameron and Trivedi 1998, Wooldridge, 2002).

### **3. Empirical Results**

In this section, the results of the univariate and bivariate Poisson QMLE results are estimated with respect to five different sources of website traffic. A univariate model of each of the log of the search volumes for the seven keyword search queries is formed for each of the five regressands in order to isolate the effect of the keyword searches.<sup>4</sup> The relationship of the five different rank regressors to the five regressands of website traffic as well as their corresponding log transformation of the keyword search volume are also examined in a bivariate Poisson QMLE model. More detail about the data is presented in Subsection 3.1, and the univariate and bivariate Poisson QMLE results are presented in Subsection 3.2.

The previously mentioned Poisson QMLE model regressions are estimated using both daily and weekly data to see whether aggregation has an effect on the empirical findings, which this paper does find and is discussed in Subsection 3.3.

#### **3.1 Discussion of Data**

When a visitor searches for a destination, he or she will be likely to type in a query in search engines, look through the returned results, and pick a webpage to follow. Thus, search volumes for certain keyword search queries and the website's ranking for those queries in major search engines will have a significant effect on the website's traffic (Pan, Litvin, and O'Donnell, 2007). This paper focuses on three variables, which are the ranking of a site for certain keyword search queries, search volumes for those queries, and online traffic for that specific website. The data used in the Poisson regressions comes from three different Google sources. The focus search engine is Google since it has dominated the market share during the period of the study, which is from January 2008 to March 2009.

---

<sup>4</sup> The level variables for the search volume of keyword queries have also been used in model estimation, but the findings do not vary significantly.

The regressands of various forms of website traffic are obtained from Google Analytics of the CACVB website. Google Analytics uses a short Javascript on every page of a website to capture visitors' visitation behavior on the website. For this paper, five regressands are specifically analyzed in this paper as is listed in Tables 1A and 1B. The first regressand, entitled *all visits*, encompasses all the website traffic to the CACVB website. A sub-category of only first visits to the CACVB website (as indentified by new internet protocol (IP) addresses) forms the second regressand of *new visits*, and website traffic that are from only search traffic via a search engine is also examined and is referred to as *search traffic*, forms the third regressand. The fourth and fifth regressands are also sub-groups of website traffic from outside the local Charleston area and is entitled *nonlocal visits* and from the local Charleston area entitled *local visits*, respectively.

The rankings of the CACVB site for five search queries in Google were obtained through a custom-built program. A program has been designed to download daily search engine results as it pertains to five different keyword search queries: *charleston sc*, *travel charleston*, *charleston hotels*, *charleston restaurants*, and *charleston tourism*. These queries are the popular searches used by visitors to Charleston, SC, according to Google Keyword Tool.<sup>5</sup>

The regressors of normalized and scaled search volumes for the five queries, during the time period of January 2008 to March 2009, are obtained from Google Insights. Google Insights is a public search tool. Since January 2004, search volumes for specific searches for up to five queries can be obtained but only for a limited time period (three months) as it might be due to the normalization and scaling processes and the protection of the privacy of Google users. The normalizing and scaling methods used for daily data changes quarterly, which is why the daily data is examined only one quarter at a time for the sake of consistency.

Sometimes in statistics, the terms normalizing and scaling are used interchangeably, but this is not the case with Google data. Regarding normalization, according to Google Insights (2009a), the raw data is sorted by a common variable

---

<sup>5</sup> The web address for Google Keyword Tool is as follows:  
<https://adwords.google.com/select/KeywordToolExternal>.

and is then normalized by the website traffic in a given region. This normalization process could mean that if two regions have the same percentage in terms of the search volumes for a given search query, this does not automatically mean that the absolute search volumes are the same. The reason for the normalization process is to prevent regions with higher search volume activity from dominating the rankings as displayed by Google Insights. The scaling process occurs after the normalization process. The scale of the data as it pertains to search volumes is from 0 to 100 with each data point being divided by the highest point as 100 (Google Insights 2009b). Aside from the normalization and scaling processes, which can produce distortions, it is possible for the aggregation of data to have an effect on the empirical findings (Rossana and Seater 1995, Pyle 1999). For this paper, aggregation refers to the frequency of the data, meaning the transformation of daily data into weekly data, which is discussed in more detail in Subsections 3.2 and 3.3.

For the regressors, the search volumes for specific keywords searches in two categories of general overall type of searches is denoted as 'all' and a subcategory of queries in just travel categories as specified by Google Trends, which is denoted as 'travel' is found in Table 1B. The search volume data for specific keyword queries is normalized and scaled by Google for both the daily data and the weekly data (Askitas and Zimmermann 2009, Google Trends 2009). The daily data has the same scale for three months, which limits the analysis of the daily datasets to only one quarter at a time. The weekly data has the same normalization and scaling regardless of quarter. The daily ranking of the CACVB website are captured using the afore-mentioned custom-built program, and the weekly data are the averages over a week's period of time.

As is shown in Table 1B, the log of the search volumes in the 'all' search category is as follows: *charleston hotels*, *charleston restaurants*, *charleston sc*, *charleston tourism*, and *charleston travel*, and the queries in the 'travel' search category is as follows: *charleston hotels*, and *charleston sc*. Google Trends did not provide the other three search traffic in the travel category due to their small volumes. The log of the scaled search volumes for the keywords searches in both the 'all' and 'travel' categories is used in the Poisson regression especially since the

coefficients of the regressors can be interpreted as elasticities, which is analogous to Equation (6). The rank variables involve the rankings of *charleston sc*, *charleston hotel*, *charleston restaurants*, *charleston tourism*, and *charleston travel*. The coefficients of these regressors are interpreted as semi-elasticities as is defined in Equation (7).

Regarding the weekly regressors, the entire period from January 2008 to March 2009 is examined simultaneously because the normalization and scaling methods are the same for the search volume variables. For the rank variables, the weekly data are the average of a seven-day week, but it should be noted that the rank variables are based upon search volume variables that have already been normalized and scaled. In regards to the Poisson regressions, both daily and weekly data are used. The number of observations for each Poisson regression is listed in Table 1A. There are some missing observations due to the temporary lack of connection to the Internet or the blockage of the custom-built program by the Google Server since the program was the suspect of spamming.

### **3.2 Interpretation of the Univariate and Bivariate Poisson QMLE Results**

The benefit of using daily data organized quarter-by-quarter is that one can observe the peak quarter of website traffic to the CACVB website with respect to keyword queries. Regarding the daily data, the general relationship between the estimated coefficients of the log of the keyword search volumes and the regressand is a positive one as is shown in Tables 2A and 2B. For instance, in the general 'all' search category of keyword searches for *charleston hotels*, the quarter that produces the largest estimated elasticity is the third quarter for all five regressands which involves all website traffic to the CACVB website and the four subcategories of website traffic to the CACVB website. This is also true for the estimated coefficients involving the log of the keyword search volumes for *charleston restaurants*, *charleston tourism*, and *charleston travel* with the peak quarter being the fourth quarter. The only keyword search query whose peak quarter shows some variation in the five Poisson regressions is that of *charleston sc*. For the regressand of nonlocal visits, the peak quarter is in the first quarter and for the remaining four regressands, the peak quarter is in the second quarter.

As for the keyword searches for *charleston hotels*, in the 'travel' category, the third quarter produces the largest estimated elasticity for all five regressands as it does in the general overall category of keyword searches. Analogous to the general overall category of keyword searches, the keyword searches for *charleston sc*, in the 'travel' categories also produces different peak quarters with respect to the regressands. Having access to which keyword searches are going to have the biggest impact at a given time could help tourist boards and businesses to maximizing their advertising expense, which is just one benefit of using Google data.

It should be noted that a few of the coefficients are negative such as in the coefficient for the log of the keyword search volumes involving *charleston restaurants* in the second quarter, but these coefficients prove to be statistically insignificant. The coefficient for the log of the keyword search volumes involving *charleston tourism* are also negative and statistically insignificant, which could possibly be due to a missing data problem since the dataset is reduced to 58 observations for the first and fifth quarter and to 83 observations for the second quarter and to 86 observations for the third and fourth quarters.

A surprise finding of this paper is the impact of the regressors of rankings on website traffic. One might assume that the ranking of a website might help draw the attention of the search engine user to a higher ranked website, but this paper finds that most of the estimated coefficients of the rank regressors are statistically insignificant or very small as is shown in Tables 2A and 2B.

For the statistically significant estimate coefficients, there generally is a negative relationship between the regressor and the regressands. For instance, looking at the fifth quarter for the rank variable of *charleston travel* with respect to the regressand of *all visits*, Table 2 shows that the estimated coefficient is -0.197, which means that the log of website traffic decreases by 19.7% if the estimated coefficient is interpreted as a semi-elasticity. Alternatively, for the fifth quarter of the rank variable of *charleston hotel* with respect to the regressand of *all visits*, Table 2 shows that the estimated coefficient is 0.020, which means that the log of website traffic increases by 2.0%. It could be said that for certain variables, where a search

engine user has something specific in mind such as a preferred hotel, rank does not help entice website traffic to a given website.

Working with rank variables is problematic, due to the lack of variability, which produced singular matrices in the Poisson QMLE results and is not reported in Tables 2A, 2B, 3, and 4 in order to conserve space. Furthermore, there is also a missing data problem, which reduced the dataset for the regressions for four quarters of daily data as well as the weekly data which involve the rank variables of *charleston sc* and *charleston hotel*. The estimated coefficients from the regressions with missing observations turned out to be statistically insignificant.

As is shown in Table 3, combining the log of the keyword search volumes with their respective ranking in the same regression did not greatly alter the empirical findings of the individual univariate regression results especially with respect to statistical significance.

### **3.3 Effects of Normalization, Scaling, and Aggregation**

The most dramatic finding of this paper is with respect to the comparison of the estimated Poisson QMLE results using daily and weekly data, which has important implications in terms of policy implementation. Generally, one would expect that if the average at a lower frequency is rather consistent, then this ought to be reflected at the higher frequency. The same should hold for conditional means as well, but this is not the case when comparing the Poisson QMLEs when using daily and weekly data. For this comparison, the average of the regression estimates for the five quarters involving daily data is compared to the regression estimates of the weekly data, which is shown in Table 4.<sup>6</sup>

In some instances, depending on the frequency of data, there is a reversal of the sign of an estimated coefficient and even statistical significance, which is what occurs for the Poisson QMLE results that involve the regressand, *local visits*. When daily data is used, the sign for all seven regressors involving the log of keyword search volumes is positive with four out of the seven Poisson QMLE regressions

---

<sup>6</sup> It should be noted that the daily data is scaled differently for each quarter, which could have an impact on the comparison, but the general overall idea should hold.

producing statistically significant coefficients. Alternatively, when weekly data is used all seven estimated coefficients are statistically insignificant, and five out of the seven estimated coefficients become negative.

When examining the goodness of fit of a model, the higher the R-squared term and the lower the Akaike Information Criteria (AIC) the better. For the seven Poisson QMLE regressions that involve *local visits*, the regressions that use weekly data produce a slightly lower AIC, but the R-squared terms are much higher when daily data is used.<sup>7</sup> This is not the case for the remaining four regressands. For the other four remaining regressands, the R-squared terms are generally higher on average and the AICs are much higher when weekly data is as opposed to daily data as is shown in Table 4. Normally, one would expect a lower AIC with a higher R-squared term, but this anomaly is discussed in more detail a little further on in this subsection.

In regards to the interpretation of the estimated coefficients, a different story emerges depending on the frequency used in the regression. For instance, examining the regression involving the regressand, *new visits*, the Poisson QMLE regression using daily data produces a statistically significant estimated coefficient of 0.749 on average for the regressor concerning *charleston sc* in the travel category, which states that the conditional mean changes proportionally by 0.749. When weekly data is used, the conditional mean, for the same regressor, changes proportionally by 1.106, which is also statistically significant. The R-squared term is approximately 50% higher and the AIC is more than three times higher in the regression involving weekly data, which is listed in Table 4.

Another such example involves the regressand, *search traffic*, and the regressor *charleston sc* in the general overall search category as is also shown in Table 4. When daily data is used, the statistically significant estimated regression coefficient is 0.984 with an R-squared term of 0.34 and the statistically significant estimated regression coefficient is 1.450 with an R-squared term of 0.39 when weekly data is used. So, it appears that in terms of explaining the variability of the

---

<sup>7</sup> For evaluating the goodness of fit of a Poisson QMLE model, Wooldridge (2002) uses the R-squared terms, while Michener and Tighe (1992) use the AIC.

regressand, *search traffic*, both daily and weekly data capture approximately the same level of variability, but the AIC terms are vastly different. When daily data is used, the AIC is 61.85 and when weekly data is used, the AIC is 418.36. So, it would appear that based on the AIC, the Poisson QMLE regression model using daily data is a better fit.

When using weekly data, the regressions produce estimated coefficients that are generally larger on average, which naturally produce larger R-squared terms. So, in terms of goodness of fit, the R-squared terms might not be necessarily the best measure, which leaves the AIC as a measure of goodness of fit of the regression models for consideration. The AIC is generally lower when daily data is used, which indicates that the daily data might give a better picture of explaining the five various forms of website traffic discussed in this paper except in the case of *local visits*. This is not a prudent conclusion to draw due to the lack of transparency of the normalized and scaled regressors especially in regards to the keyword search volumes.

Hence, in the examination of the relationship between various types of website traffic and the regressor of the log of keyword search volumes, a different picture unfolds depending on the frequency of data used.

#### **4. Conclusion**

The benefit of using data from Google Insights and Google Trends for businesses is that it can better help businesses to target certain markets by providing instantaneous access to the most current data available at any given time. Using data from Google Insights and Google Trends is also helpful to researchers by providing a consumer-driven data source, i.e. internet activity, to help explain or predict economic activity without the time lag required for economic time series such as unemployment statistics.

Alternatively, using data from Google Insights and Google Trends can also be problematic due to the lack of transparency in regards to the normalizing and scaling of Google data as is demonstrated in this paper with the drastically different

empirical findings of the Poisson QMLE results that are obtained using both daily and weekly data.

A suggestion for future research involving Google data would be to work with the raw data that can be aggregated according to the researcher's needs as is done with many economic time series provided by the Federal Reserve or the Bureau of labor Statistics, for instance. In doing so, a researcher could still have the problem of aggregation in regards to the empirical results, but the potential doubts on the empirical findings caused by normalizing and scaling would at least be removed. However, privacy concerns might prevent search engine companies to do so due to recent controversies on revealing a user's search history through search log data (Barbaro and Zeller 2006). Balancing the great potential for research which could benefit the consumers versus the protection of user privacy will be the key to the future development in this research area.
