# **Estimates of the Fiscal Impact Multiplier**

## **in Reduced-Form Equations**

(Working paper)

Stefan Belliveau

### i. ABSTRACT.

An analysis of the multiplier for the US federal government's consumption expenditures is presented. A simple approach to identify the influence of the federal government's consumption expenditures on economic activity using reduced-form equations is clearly presented and examined using annual US data from 1929-2011. The conclusion from this analysis is that estimates from reduced-form equations can inform fiscal-policy decision making.

ii. KEY WORDS: Business cycles, fiscal policy

iii. JEL CODES: E32, E62

## 1. INTRODUCTION.

Recent economic development raises questions for policymakers about whether and how to respond. Economic theory has informed analysis that supports various fiscal-policy responses, including nonresponse by reason of no effect, stimulative fiscal response, and fiscal discipline as a response. Fiscal nonresponse is supported by economic theory which concludes that economic variables measuring such policy's action have no influence on a real economy. Stimulative fiscal response is supported by economic theory informed by Keynesian conclusions (e.g., the New Keynesian theory), where economic conditions may be augmented for a time by fiscal policy in such a way that fiscal policy as generally understood is a viable option. The response of fiscal discipline to poor economic conditions is informed by economic theory that hypothesizes that reducing government expenditures for a given government fiscal position will improve economic conditions. The structure of this paper's analysis is intended to show that analysis of reduced-form equations can inform a fiscal-policy decision-making process.

The structure of this working paper follows: this introduction followed by a brief exploration of the economic data, a presentation of reduced-form equations and their estimates, a summary, all tables and figures cited, a list of references, and a list of the data sources.

## 2. EXPLORATION OF THE ECONOMIC DATA.

Economic activity appears to rise and fall in a cyclical pattern. Reference to a business or economic cycle is common in both general news media and scholarly economic journals. Figure 1 shows measures and analysis of US economic activity for a long period. The solid black line depicts annual US real output on a logarithmic scale (left axis). This scale allows a linear view of an exponential process (i.e., economic growth). Presented over a long duration, it suggests an underlying process that is steady. The dashed line portraying the trend of real output on a logarithmic scale with

respect to time makes this explicit.

The shaded area in Figure 1 depicts deviation of real output from its (logarithmic) linear trend with respect to time in percent (right axis). It can be interpreted as a barometer of economic activity. This barometer of economic activity begins positive in 1929, sharply declines in the years 1930-3, rises greatly in the years 1941-4, again declines sharply in the years 1946-7, remains positive for all years 1950-81, and is sometimes negative for years 1982-2011. This is a reasonable measure of US economic activity for the period.

Comparisons showing how economic activity behaves while government spending fluctuates are presented to examine whether or not there is any relationship present. Table 1 lists the ten largest absolute changes to nominal federal consumption expenditures for the years 1929-2011 when measured as a percent of nominal output. Figure 2 compares economic activity with changes to federal government consumption expenditures in the years 1936-52, the range of years with the 10 largest absolute changes to nominal federal consumption expenditure when measured as a percent of nominal output.

Figure 2 shows that during the years with the largest changes to federal consumption expenditures as a percent of nominal output, there is a positive relationship between changes in real output and changes to federal consumption expenditures. During these years the mean of federal consumption expenditures as a percent of nominal output is 11.5, with large variation. This exploration of the economic data is suggestive, but insufficient of its own to inform policy decision making. It shows that at the end of the 1930s, after roughly a decade of poor economic performance, a large and (positive) exogenous shock to federal government purchases was coincident with improved economic conditions (see Figure 1). In narrowly defined economic terms this spending was largely wasteful (i.e., purchases of munitions and other war materials), yet economic conditions improved.

Restricting analysis to one country could limit its conclusions, as there are many factors that

undoubtedly influence the measure of real gross domestic product. Additional factors may include monetary policy and inflation. Therefore, this paper will include a brief exploration of international economic data to examine if the US is a special case among developed economies with respect to the relationship between government consumption expenditures and real output.

Countries that adopted the Euro as a common currency accept identical monetary policy and similar rates of inflation. This makes the countries of this currency union especially useful to explore for comparison purposes, because conclusions based on cross-section analysis of these countries' economic data cannot be attributed to differences in monetary policy for the period of common currency. This is a control for differences in monetary policy.

Figure 3 compares changes in real output with changes to nominal government final consumption expenditures for the years 2007-10.<sup>1</sup> The selection of countries includes those in the economic and monetary union which adopted the Euro as common currency no later than 31 December 2006 (minus Cyprus and Malta) plus the US for comparison. Germany is plotted in yellow as a reference point, being the largest economy in the currency union. The US is plotted in blue for comparison. There is a positive relationship depicted between changes to nominal government final consumption expenditures and changes in real output. This analysis offers no support that the US is a special case with respect to the relationship between government consumption expenditures and real output.

### 3. REDUCED-FORM EQUATIONS.

Exploratory analysis of the economic data shows a positive relationship between changes to nominal government consumption expenditures and changes in real output, suggesting a viable role for fiscal policy. However, this cursory analysis is possibly deficient because there may exist excluded

---

<sup>1</sup> Comparable data for 2011 were not available from the source at the time of this analysis. Data for Cyprus and Malta were also not available.

factors that are co-varying with changes to nominal government consumption expenditures and determining. Analysis in this section will address such potential deficiency in an attempt to reduce bias from excluded factors and endogeneity.

The timing of large changes to nominal defense consumption expenditures, occurring when international relations break down (e.g., a war), is less likely than of total nominal federal consumption expenditures to be influenced by changes in other economic measures. Changes to nominal defense consumption expenditures will be used therefore to estimate the impact from changes to total nominal federal consumption expenditures in order to reduce bias from possible endogeneity. This approach has been used previously by Ramey.<sup>2</sup>

This paper's analysis will estimate the percent change in real output in terms of a change equal to 1% of nominal output in the economic measure analyzed.<sup>3</sup> This is the definition of a multiplier for an economic measure henceforth herein. Equation (1) is used when estimating the short-run trade-off between output and inflation:

$$(1) y_t = \alpha + \beta \Delta x_t + \gamma y_{t-1} + \delta t ,$$

where the log of real output is regressed on the change in nominal output, its own lag, and a time trend.

<sup>4</sup> This equation estimates real output as a function of change in nominal output, the assumption being that the effect not captured by real output is lost to inflation.

Taking instead the first difference of all terms and dropping the differenced time trend gives:

$$(2) \Delta y_t = \alpha + \beta \Delta x_t + \gamma \Delta y_{t-1} ,$$

which has the form of a dynamic regression model. Analysis now continues by substituting relevant economic measures for change in nominal output (i.e., for the term  $\Delta x_t$  in equation (2)).

The first measures to substitute for change in nominal output are change to nominal defense

---

2 Use of a reference to this work was made in another reference used.

3 The interval between observations is one year; the impact / short-run multiplier will be estimated.

4 See Ball et al. (1988).

consumption expenditures and change to nominal business investment:

$$(3) \Delta y_t = \alpha + \beta_1 \Delta(\text{NDC:Y})_t + \beta_2 \Delta(\text{I:Y})_t + \gamma \Delta y_{t-1} .$$

Change to nominal defense consumption expenditures is the proxy chosen for change to total nominal federal consumption expenditures, while change to nominal business investment is selected to reduce the potential for bias from excluded factors. Table 2 summarizes the OLS regression results for equation (3).<sup>5</sup> Included in Table 2 are regression results for the years 1929-54 (these years include large changes to nominal defense consumption expenditures resulting from WWII and the Korean War). The estimated coefficients for defense consumption expenditures and business investment are similar. These coefficients are equivalent to the definition of multiplier stated previously and both estimates are significantly greater than one. This type of analysis could be used to inform fiscal-policy decision making.

Economic theory predicts that a fiscal multiplier will not remain constant through time. Some reasons are that government expenditure is subject to diminishing returns, that inflation will ensue per the well-known relationship expressed in the Phillips Curve, and that crowding out of private investment will occur. A static estimate of a fiscal multiplier with respect to time is therefore possibly deficient. Equation (4) allows for an estimate of a non-static fiscal impact multiplier:

$$(4) \Delta y_t = \alpha + \beta_1 \Delta \text{ndc}_t + \beta_2 \Delta i_t + \gamma \Delta y_{t-1} .$$

Both defense consumption expenditures and business investment as shares of nominal output are replaced in equation (4) by their logs.

The OLS regression estimates are found in Table 3.<sup>6</sup> Included in Table 3 are regression results

---

5 The Breusch-Godfrey Lagrange-multiplier statistic (through order 5) for the regression estimation is not significant at the 10% level given the standard null hypothesis for the years 1929-2011. The Breusch-Pagan Lagrange-multiplier statistic for the regression estimation is significant at the 5% level for the years 1929-2011; estimates of robust standard error with respect to heteroscedasticity are included.

6 The Breusch-Godfrey Lagrange-multiplier statistic (through order 5) for the regression estimation is not significant at the 10% level given the standard null hypothesis for the years 1929-2011. The Breusch-Pagan Lagrange-multiplier statistic for the regression estimation is significant at the 5% level given the standard null hypothesis for the years 1929-2011; estimates of robust standard error with respect to heteroscedasticity are included.

for the years 1929-54. Given the respective levels of defense consumption expenditures and business investment during the years 1929-2011, these estimates are similar with respect to the relative size of implied impact to those from Table 2. Figure 4 shows the fiscal impact multipliers that result from the relevant estimate of equation (4) compared with the level of nominal defense consumption expenditures for the years 1947-2011.

An inverse relationship between the fiscal impact multiplier and nominal defense consumption expenditures is depicted now. Analysis supports that for most ranges of federal government expenditures observed, fiscal policy's estimated potential impact on total output is greater than one; for a few observed levels its estimated potential impact is less than one but greater than zero; and for no observed levels is its estimated potential impact zero (although theoretically it is possible at the zero asymptote). This particular analysis supports the viability of fiscal response, caveatted by stating that the size of government expenditures relative to total output is a limiting factor, and it supports the response of fiscal discipline in rare circumstance. Again, such analysis could be used to inform a fiscal-policy decision-making process.

Concurrent action by monetary authorities could have an effect on the potential impact from a policy where government expenditures are deliberately shocked. For example, if a monetary authority purchases the debt issued to pay for a fiscal response, some economic theory suggests that this would be additionally stimulative.<sup>7</sup> This effect will be referred to as monetization, and equation (5) includes measures to estimate this effect:

$$(5) \Delta y_t = \alpha + \beta_1 \Delta(\text{NDC:Y})_t + \beta_2 \Delta(\text{I:Y})_t + \beta_3 \Delta h_t + \beta_4 \Delta \text{MM}_t ,$$

where “h” is the log of high-powered money and “MM” is the M1 multiplier. Table 4 shows estimates for both OLS and generalized least squares regressions (functionally equivalent to a model with form

---

<sup>7</sup> Financial intermediaries and holders of deposits are assumed to co-influence this effect on the impact.

ARMAX) for the years 1929-2011.<sup>8 9</sup>

Figure 5 shows estimated multipliers for monetization compared with the level of high-powered money. This analysis, informed by economic theory, estimates an inverse relationship between the multiplier and the level of high-powered money. This analysis supports the hypothesis that there is a joint outcome between fiscal policy and the effect of debt monetization.

Equation (6) is included to produce estimates comparable with previously published estimates:

$$(6) \Delta y_t = \alpha + \beta_1 \Delta h_t + \beta_2 \Delta h_{t-1} + \gamma_1 \Delta ndc_t + \gamma_2 \Delta ndc_{t-1} + \delta_1 \Delta MM_t + \delta_2 \Delta MM_{t-1} .$$

This equation is a variation of the St. Louis Equation.<sup>10</sup> Table 5 shows estimates for both OLS and generalized least squares regressions for the years 1929-2011.<sup>11 12</sup>

#### 4. SUMMARY.

An exploration of the economic data demonstrated a positive relationship between economic activity and government consumption expenditures. This relationship was shown in the US and among developed economies with a common currency. Cross-section analysis did not support that the US was a special case with respect to the relationship between government consumption expenditures and economic activity. The narrative attributing economic recovery from the Great Depression to a large exogenous shock to government expenditures is congruous with the economic data. It was noted that mere correlation between one economic measure and economic activity is insufficient to inform policy decision making.

---

8 The Breusch-Godfrey Lagrange-multiplier statistic for the OLS regression estimation is significant at the 10% level given the standard null hypothesis. The Breusch-Pagan Lagrange-multiplier statistic for the OLS regression estimation is not significant at the 10% level given the standard null hypothesis.

9 The mean estimate is deliberately omitted.

10 See Andersen and Jordan (1968).

11 The Breusch-Godfrey Lagrange-multiplier statistic for the OLS regression estimation is significant at the 5% level given the standard null hypothesis. The Breusch-Pagan Lagrange-multiplier statistic for the OLS regression estimation is not significant at the 10% level given the standard null hypothesis.

12 The mean estimate is deliberately omitted.

Caution was taken in the analysis in order to reduce bias and increase efficiencies of the regression estimates. A proxy for government consumption expenditures that is less likely to be influenced by other economic factors was incorporated into the analysis in order to reduce the potential for bias from endogeneity. A measure of nominal business investment was included in the analysis specifically as a means to minimize bias from excluded factors. Given known issues of autocorrelation and heteroscedasticity with time-series econometric analysis, procedures were used to identify potential issues and to mitigate their effects.

The use of reduced-form equations and measures of monetary aggregates in econometric analysis is not popular currently. Instead, simulations (e.g., dynamic stochastic general equilibrium models) and policy rules incorporating interest-rate targeting are preferred. This working paper's analysis broadens the current literature by applying concepts that are no longer widely applied, yet at one time had more influence. A recent work summarizes estimates of the one-year government-consumption multiplier from various structural policy models; the range for the average of estimates in various scenarios given monetary accommodation is 1.2 to 1.55.<sup>13</sup> This range is quite similar to static estimates of the fiscal impact multiplier from this working paper's analysis.

Analysis from reduced-form equations can inform a decision-making process for considering fiscal-policy response. Figure 6 shows estimates of the impact multipliers for fiscal and monetary policy responses from reduced-form equations for the years 1929-2011.<sup>14</sup> When considering the effects to policy given uncertainty, it is plausible that a decision-making process informed by more estimates will be superior to one informed by less.

---

13 See Coenen et al. (2012)

14 Both estimates are scaled such that their respective average of values in years 1999-2000 equals 1. A reported value of 1 in Figure 6 does not imply that the corresponding estimate is 1.
