Abstract

In this paper, we revisit the well-known UK inflation model by Hendry (*Journal of Applied Econometrics* 2001, 16:255-275. doi: 10.1002/jae.615). We replicate the results in a narrow sense using the gret1 and PcGive programs. In a wide sense, we extend the study of model uncertainty using the Bayesian averaging of classical estimates (BACE) approach as automatic model reduction strategy. We consider three different specifications to compare BACE variable selection with Hendrys' reduction. We find that BACE method can recover the path of non-trivial reduction strategy.

Keywords: BACE, gretl, model uncertainty, reduction strategy

1 Introduction

This paper concerns a replication of a model of UK inflation, 1875–1991, by Hendry (2001) based on data provided by JAE services at (http://qed.econ.queensu.ca/jae/2001-v16.3/hendry). To replicate Hendrys' procedure for modeling inflation in the UK in a narrow sense, we used the gretl¹ (see Cottrell & Lucchetti, 2018) and PcGive/Autometrics (see Doornik, 2009) program². Our extension, in a wide sense, of Hendrys' work employed the Bayesian averaging of classical estimates (BACE) approach proposed by Sala-i-Martin, Doppelhofer, and Miller (2004) to compare model reduction strategies and the variable selection procedure.

¹Gretl is an open-source software for econometric analysis available at http://gretl.sf.net.

²We used gretl version 2019a and PcGive version 14.2 with Ox Professional version 7.20 on a PC machine running under Debian GNU/Linux 64 bit.

When we consider the large number of variables, it is difficult to decide which model is the most appropriate for analyzing the dependencies, i.e., to find the optimal set of variables in terms of goodness of fit measures. Using BACE, we can obtain the most probable set of determinants along with posterior parameter estimates based on the whole model space instead of making decisions based only on a single model. This approach is an alternative to the earlier and familiar Bayesian model averaging (BMA) (see Fernández, Ley, & Steel, 2001; Ley & Steel, 2012), from which it differs by having non-informative prior assumptions of regression parameters. Discussion on the effect of prior assumptions in BMA is presented in Ley and Steel (2009). Sala-i-Martin et al. (2004) showed that the BACE approach may be understood as Bayesian analysis in the situation where prior information is "dominated" by the data. The parameter estimates are averaged across all possible combinations of models obtained by means of OLS. In our case, the BACE analysis was performed in the BACE 2.0 package for the gret1 program³ (see Błażejowski & Kwiatkowski, 2018).

The remainder of the paper is structured as follows. In section 2, we discuss issues related to data transformation, section 3 presents the research scenario for the replication in a narrow sense. In section 4 we consider model uncertainty using BACE selection strategy (replication in a wide sense), section 5 concludes.

2 Data

In our paper and replication files, we used the same data sample period (1875-1991) and definitions as in Hendry $(2001)^4$ with the following exceptions:

- 1. *Profit markup* (π_t^*) was taken directly from the jaedfh4.dat file (part of the dfhdata.zip archive); this variable exists as "pistarn" in the JAE archive.
- 2. Short-long spread $(R_{s,t} R_{l,t} + 0.006)$ was named S_t , similar to Clements and Hendry (2008, pp. 11).
- 3. Excess demand (y_t^d) was taken directly from the jaedfhm.dat file (part of the dfhdata.zip archive); this variable exists as "gdpd" in the JAE archive.
- 4. The real exchange rate was defined as $e_{r,t} = p_t p_{\pounds,t} 0.52$. We found an inaccuracy in the paper by Hendry (2001) and data definitions in the JAE archive. The calculation of $e_{r,t} = p_t p_{\pounds,t} + 0.52$ (equation (3) in Hendry (2001, pp. 263)) is misleading with the form of calculating $e_{r,t}$ in the formula for "pistarn" (readme.h.txt file) and refers to subtracting (not adding) the intercept value (0.52).
- 5. According to formulas in the JAE archive (readme.h.txt file), the variable Unit labor costs in constant prices was defined as $(c-p)_t^* = c_t p_t + 0.006 \times (trend 69.5) + 2.37$.

3 Research scenario

To replicate the Hendry (2001) results in a narrow sense, we proceed as follows. In the case of the initial model for all 52 variables, we received identical output to that in the original model (GUM52; residual standard deviation $\hat{\sigma} = 1.21\%$,

³The BACE 1.2 package is available at http://ricardo.ecn.wfu.edu/gretl/cgi-bin/gretldata.cgi?opt=SHOW_FUNCS.

⁴Description of variables are available in table 6 in Appendix.

Schwartz Criterion SC = -7.3). After excluding indicators from the initial model, we also received identical results (GUMnoIndicators; $\hat{\sigma} = 2.5\%$, SC = -6.63). In the next step, we added dummy variables I_b , I_l , I_m concerning outliers in particular years to (GUMnoIndicators), and we obtained the same results as in the paper (GUMfirstReduction; $\hat{\sigma} = 1.16\%$, SC = -8.08). In the next step, the dummy variables I_b , I_l , I_m were substituted by one overall index, I_d , and once again, we obtained the same results (GUMsecondReduction; $\hat{\sigma} = 1.15\%$, SC = -8.16). Finally, we expressed the general model in terms of π_{l-1}^* with indicators restricted to I_d (GUMfinal; $\hat{\sigma} = 1.15\%$, SC = -8.33). At this point, we had the following specification:

$$\Delta p_{t} = f(\Delta p_{t-1}, y_{t-1}^{d}, m_{t-1}^{d}, n_{t-1}^{d}, U_{t-1}^{d}, S_{t-1}, R_{l,t-1}, \Delta p_{e,t}, \Delta p_{e,t-1}, \Delta U_{r,t-1}, \Delta u_{r,t-1}, \Delta w_{t-1}, \Delta c_{t-1}, \Delta m_{t-1}, \Delta R_{s,t-1}, \Delta R_{l,t-1}, \Delta p_{o,t-1}, I_{d,t}, \pi_{t-1}^{*}; \varepsilon_{t}).$$
(1)

After the reduction of model (1) at a 1% significance level⁵, we obtained Hendrys' model (6) (Hendry, 2001, pp. 267) and (FinalModel; $\hat{\sigma} = 1.14\%$, SC = -8.66) in our notation. Detailed results are available in the table 1.

	r r	,, ,

Table 1: Comparison of Hendrys' estimates and the replication results

Standard errors in parentheses.

According to results in table 1, we found minor differences in the coefficient estimates for four variables— y_{t-1}^d , Δm_{t-1} , $\Delta R_{s,t-1}$, and Δp_{t-1} —and two differences in standard errors for S_{t-1} and Δp_{t-1} . The remaining coefficients and the model statistics were identical. In his paper, Hendry used the PcGets automatic model selection procedure with a 1% significance level for the model (1) to check the correctness of the simplification⁶. We repeated this automatic model selection procedure using Autometrics for model (1), and we obtained the same estimates as in GUMfinal in gretl (i.e., with slight differences compared to model (6) in Hendrys' paper). We suppose that these differences are due to the precision of the computers used for calculations, the 32 or 64 bits software or precision involved in data storage.

⁵Hendry and Krolzig (2001) classified simplification at a 1% significance level as a "conservative" strategy and at a 5% significance level as a "liberal" strategy. Currently these strategies are renamed the "small" and "standard" target size (see Doornik & Hendry, 2013).

⁶See subsection 4.3 in Hendry (2001).

4 BACE analysis

In order to perform replication in a wide sense, we analyzed model selection procedure employing the BACE approach. This procedure enables searching the whole model space and selecting the most probable regressions. The BACE also enables calculations of the averages of the posterior means and standard deviations of parameters as well as posterior inclusion probabilities (PIP). The posterior inclusion probability is the probability that, conditional on the data but unconditional with respect to the model space, the independent variable is relevant in explaining dependent variable. PIP is calculated as the frequency of appearance in Marcov chain of a given variable in all considered models (see Doppelhofer & Weeks, 2009; Koop, Poirier, & Tobias, 2007). We assumed three scenarios for BACE analysis:

- 1. GUM52—we used all 52 available explanatory variables (including trend and outliers).
- 2. GUMId—we used I_d composite indicator which captures the 22 large outliers and elements of π^* .
- 3. GUMfinal—we used I_d and π^* variables.

4.1 GUM52 results

We formulated the following initial inflation model (GUM52) for the UK in 1875-1991:

$$\Delta p_{t} = f \left(\Delta p_{t-1}, y_{t-1}^{d}, m_{t-1}^{d}, n_{t-1}^{d}, U_{t-1}^{d}, e_{r,t-1}, c_{t-1}, S_{t-1}, p_{t-1}, p_{o,t-1}, R_{l,t-1}, \Delta p_{e,t-1}, \Delta p_{e,t}, \Delta u_{r,t-1}, \Delta w_{t-1}, \Delta c_{t-1}, \Delta m_{t-1}, \Delta R_{s,t-1}, \Delta R_{l,t-1}, \Delta p_{o,t-1}, trend, outliers; \varepsilon_{t} \right).$$
(2)

Trend, individual-year indicators (outliers) and the rest of the variables, are defined identically as in Hendry (2001). The whole model space in GUM52 (including intercept) was equal to $2^{52} = 4,503,599,627,370,496$. The total number of Monte Carlo iterations was 5,000,000 (including 25% burn-in draws). Model prior was set to uniform, which means that all possible specifications are equally probable (or, in other words, we do not prefer any of 2^{52} possible specifications). Additionally we performed jointness analysis based on J_{LS} measure introduced in Ley and Steel (2007), because it can identify independence, substitutes and complements between variables in the regression model (see Doppelhofer & Weeks, 2009).

Results of BACE analysis for the GUM52 are in table 2. We can draw the following conclusions:

- 1. We found that 6 out of 7 variables from Hendrys' final model (excluding I_d and π^*) are highly probable (PIP $\ge 2/3$). The 7th variable, i.e. y_{t-1}^d (GDP excess demand), is lowly probable (PIP < 1/3). Instead of y_{t-1}^d we obtained Δn_{t-1} (nominal National Debt), which is classified as medium probable variable $(1/3 \le \text{PIP} < 2/3)$. We can find a possible explanation of this discrepancy using jointness analysis. According to jointness results, variable y_{t-1}^d is a strong substitute for Δn_{t-1} with value of $J_{LS}(y_{t-1}^d, \Delta n_{t-1}) = -2.0431$ (Doppelhofer & Weeks, 2009), hence we can say that these two variables swap between each other.
- 2. Individual-year indicators can be divided into three groups:

	PIP	Avg. Mean	Avg. Std. Dev.		PIP	Avg. Mean	Avg. Std. Dev.	
<i>I</i> ₁₉₂₁	1.0000	-0.1522	0.0194	Δn_{t-1}	0.5937	0.0357	0.0378

Table 2: BACE posterior inclusion probabilities and posterior estimates of regression coefficients for the GUM52

- (a) highly probable: 1880, 1881, 1900, 1915, 1917, 1919, 1920, 1921, 1922, 1940, 1942, 1943, 1945, 1970, 1971, 1973, 1975, 1980 (18 variables).
- (b) medium probable: 1916, 1939, 1944 (3 variables).
- (c) lowly probable: 1901, 1914, 1918, 1941, 1946, 1974, 1979 (7 variables).

The results coincided with a set of variables included into composite indicator I_d which captures the 22 large outliers. The only exception is the indicator for 1918, which according to our analysis is lowly probable (PIP_{*I*1918} \approx 0.31).

3. Although the π^* is not directly present in the GUM52, variable e_r (being an element of π^*) is also highly probable (PIP $_{e_r} \approx 0.81$).

In our opinion BACE variable selection results for GUM52 are close to Hendrys' final selection. It is worth to mention that these two selections can not be compared directly, because in GUM52 we do not have two important components, i.e. I_d and π^* , since we considered their elements separately. Having the above in mind we are convinced that in order to maintain the comparability of results we should replace individual-year indicators by the I_d composite indicator and include elements of π^{*7} .

⁷Profit markup is defined as follows: $\pi_t^* = 0.25e_{r,t} - 0.675(c-p)_t^* - 0.075(p_o-p)_t + 0.11I_{2,t} + 0.25$ where $(c-p)_t^* = c_t - p_t + 0.006 \times (trend - 69.5) + 2.37$.

4.2 GUMId results

Since BACE results for GUM52 exhibit the important role of individual-year indicators, we decided to include the I_d composite indicator as defined in Hendry (2001, pp. 266). Additionally, we reconstructed variables used in π^* according to Hendry (2001, pp. 267) to make results more comparable with GUMfinal. As a result we replaced variables c and p_o by their equivalents in constant prices, i.e. $(c - p)^*$ and $(p_o - p)$ respectively and we included lagged I_2 , so we got the following model specification (GUMId):

$$\Delta p_{t} = f \left(\Delta p_{t-1}, y_{t-1}^{d}, m_{t-1}^{d}, n_{t-1}^{d}, U_{t-1}^{d}, e_{r,t-1}, S_{t-1}, R_{l,t-1}, \Delta p_{e,t}, \Delta p_{e,t-1}, \Delta U_{r,t-1}, \Delta w_{t-1}, p_{t-1}, \Delta c_{t-1}, \Delta m_{t-1}, \Delta n_{t-1}, \Delta R_{s,t-1}, \Delta R_{l,t-1}, \Delta p_{o,t-1}, I_{2,t-1}, (c-p)_{t-1}^{*}, (p_{o}-p)_{t-1}, I_{d,t}; \varepsilon_{t} \right).$$
(3)

The whole model space in GUMId (including intercept) was equal to $2^{24} = 16,777,216$. Model prior was set to uniform and the total number of Monte Carlo iterations was 1,000,000 (including 25% burn-in draws). The posterior results are in table 3.

Table 3: BACE posterior inclusion probabilities and posterior estimates of regression coefficients for the GUMId

According to results presented in table 3, BACE procedure gives the same set of UK inflation factors as in Hendry (2001). Variables selected in model (6) in Hendry (2001) are top 8 most probable variables with PIP > 0.988. The next 5 most probable variables indicated by BACE procedure are elements of π^* .

4.3 GUMfinal results

In the next step we considered scenario using I_d and π^* directly. The BACE analysis was performed for the set of 20 variables (including the intercept) defined in GUMfinal (model (1)), so the total number of possible models was $2^{20} = 1,048,576$. We assumed that all possible specifications were equally probable. The BACE results, obtained after 1,000,000 Monte Carlo iterations, are presented in table 4.

		PIP	Avg. Mean	Avg. Stu. Dev.

Table 4: BACE posterior inclusion probabilities and posterior estimates of regression coefficients for the GUMfinal

According to the results in table 4, the set of variables used in the BACE analysis can be divided into 3 groups: highly probable determinants ($\pi_{t-1}^*, I_{d,t}, \Delta p_{e,t}, S_{t-1}, \Delta p_{t-1}, y_{t-1}^d, \Delta R_{s,t-1}, \Delta m_{t-1}, \Delta p_{o,t-1}$) with PIP \geq 0.987, medium probable (U_{t-1}^d) with PIP = 0.61 and lowly probable ($n_{t-1}^d, R_{l,t-1}, \Delta R_{l,t-1}, \Delta p_{e,t-1}, m_{t-1}^d, \Delta U_{r,t-1}, const, \Delta c_{t-1}, \Delta n_{t-1}, \Delta w_{t-1}$) with PIP \leq 0.195. Our results are consistent with Hendrys' paper because the highly probable determinants according to the BACE approach are the same as in model (6).

In addition, BACE approach allows models to be ranked according to their posterior probabilities. Table 5 presents the posterior probability, coefficient estimates and model statistics for the top 10 models. The most probable model M_1 has the posterior probability 0.200. The second probable model M_2 , with probability 0.095, is model (6) in Hendry (2001) and FinalModel in our notation. These two best models differ only by the variable U_{t-1}^d , i.e., the excess labor demand. Although the posterior probability of the highest ranked model M_1 was more than twice as large as that for the second model M_2 , an inference based only on M_1 leaves out 80% of the posterior probability mass. The "conservative" model reduction strategy dropped U_{t-1}^d , leading to M_2 , while the "liberal" strategy leads to M_1 , which includes U_{t-1}^d . This result confirms that the "conservative" model reduction strategy is relevant in the case of modeling UK inflation. Variable U_{t-1}^d with PIP = 0.61 can not be classified as a highly probable determinant, which confirms that this variable should be dropped from FinalModel. The posterior probabilities of the other models $P(M_3 | y), \ldots, P(M_{10} | y)$ are less than 0.038. These models differ from the two best models only by the least probable variables, and they do not contribute substantial

information in this case.

5 Conclusions

Replication of Hendrys' model (6) for UK inflation in a narrow sense was performed in two alternative programs (gretl and PcGive/Autometrics) and brought the same results, in line with the original paper. In our opinion slight differences comes from the precision of the computers architecture used for calculations or changes in data storage. In the replication in a wide sense, we used BACE as an automatic variable selection procedure. Taking into account the whole model space, we obtained the same set of determinants as in Hendrys' paper. All considered specifications (GUM52, GUMId and GUMfinal) indicate almost the same set of significant variables. The only difference was for specification with initial set of all 52 variables (GUM52), where the nominal National Debt was replaced by GDP excess demand, but referring directly to the findings from jointness results these variables were strong substitute. BACE selection strategy for two other specifications (GUMId and GUMfinal) gave the same set of relevant variables in explanation of UK inflation as in Hendry (2001). According to our research, BACE selection procedure recovered the path of reduction strategy used in the original paper. Moreover we can say that BACE, which takes into account model uncertainty, can properly select significant factors from the wide range of possible determinants.
