Abstract

An emerging literature estimates air pollution's effects on productivity but only for small groups of workers of particular occupations or firms. To provide more comprehensive estimates necessary for nationwide policy analysis, we estimate effects for a nationally representative sample of China's manufacturing firms from 1998 to 2007 and capture all channels by which pollution influences productivity. We use thermal inversions as an instrument to estimate the causal effect of pollution on productivity. A one $\mu g/m^3$ decrease in $PM_{2.5}$ increases productivity by 0.82% with an elasticity of -0.44. Firms respond by hiring more workers attenuating the elasticity to -0.17. Using the differential effect of China's accession into the WTO on coastal versus inner regions, we estimate the causal effect of output on pollution (elasticity of 1.43) to simulate the dynamic, general-equilibrium effects of $PM_{2.5}$ yielding an elasticity of -0.28. An exogenous 1% decrease in $PM_{2.5}$ nationwide increases annual productivity by CNY 35.9 thousand for the average firm and CNY 5.7 billion or 0.039% of GDP nationally.

1 Introduction

An emerging literature documents the effect of air pollution on short-run productivity, an important driver of economic growth. These papers significantly advance our understanding of how pollution affects productivity and convincingly demonstrate that air pollution can decrease productivity. However, because these studies utilize detailed measures of hourly or daily output per worker, they focus on narrow groups of workers in particular occupations such as fruit picking (Graff Zivin and Neidell, 2012), garment assembly (Adhvaryu *et al.*, 2019), pear packing (Chang *et al.*, 2016), call center services (Chang *et al.*, 2019) or textile assembly (He *et al.*, 2019). While these estimates are useful for evaluating narrowly-targeted environmental policies or evaluating the costs and benefits for certain groups, their external validity is of concern in evaluating broad-based pollution reduction policies.

We provide comprehensive, nationwide causal estimates of air pollution's effect on short-run productivity for manufacturing firms in China encompassing all channels of effects. Using satellite data to measure pollution we are able to consider all firms in China's manufacturing survey. The survey includes all state-owned enterprises (SOEs) and all non-SOEs with more than CNY 5 million in annual sales rendering evaluations of nationwide environmental policies feasible. For our partial-equilibrium estimates, we find an elasticity of productivity with respect to pollution of -0.44 for particulate matter less than 2.5 micrometers in diameter ($PM_{2.5}$). Holding inputs constant, an exogenous 1% increase in $PM_{2.5}$ nationwide decreases the average firm's output by USD 7.4 (CNY 56.3)[1] thousand and decreases output across all firms by USD 1.2 billion annually (0.060% of China's average gross domestic product (GDP) over the sample period). Firms compensate for this productivity loss by hiring more workers which partially offsets it. The combined effect of the productivity loss and additional hiring is an elasticity of -0.17 for output with respect to pollution. We do not find significant differences in these effects between China's major manufacturing centers and elsewhere.

Since previous papers focus on small sets of firms or workers, general-equilibrium effects could be ignored. To obtain general-equilibrium effects, we combine this estimate with an estimate of output's effect on pollution to simulate an integrated assessment model (IAM) of China's economy that combines a standard growth model with a pollution-damage function. To obtain a causal estimate of output's effect on pollution, we use China joining the World Trade Organization (WTO) in 2001 as an exogenous shock to output for firms in China's coastal regions relative to that in its inner regions – an approach widely used in the trade literature. This yields an elasticity of $PM_{2.5}$ with respect to output of 1.43. This estimate is useful in and of itself as there are few causal estimates of output's effect on pollution.

---

[1] Throughout the paper we measure output by value added and use these terms interchangeably since we abstract from intermediate inputs. A 2007 exchange rate of 7.6 is used throughout the paper.

We combine these partial equilibrium estimates and other realistic parameters to calibrate the IAM to economy-wide data during our sample period. From this we simulate counterfactuals quantifying how pollution affects output incorporating both productivity and labor supply responses. A 1% increase in $PM_{2.5}$ over the sample period decreases total output by 0.28% on average over the sample period. Exogenously reducing $PM_{2.5}$ by 1% increases the average firm's output by CNY 35.9 (USD 4.7) thousand annually and increases output across all firms by CNY 5.7 (USD 0.75) billion annually or 0.039% of China's GDP. The dynamic effects exceed the static, partial-equilibrium effects because consumers favor current consumption relative to future and sacrifice capital investment. The diminished capital accumulation results in a larger percentage drop in output relative to a static setting in which all current output is consumed. These are significant effects and can be used in cost-benefit analyses of nationwide environmental policies.

The primary obstacles in estimating pollution's effect on output are simultaneity and omitted-variable biases. Simultaneity bias in ordinary least squares (OLS) estimates could result from the production process itself in the absence of any effect of pollution on productivity or from compensating actions taken by firms in the presence of such effects. In the absence of any effects the more output a region's firms produce the worse its pollution, biasing OLS estimates upward towards or above zero. If pollution lowers productivity, this will lower output and pollution biasing OLS estimates downward. Bias may also result if firms compensate by substituting to other inputs: upward if these are low-polluting or downward if high-polluting. Omitted variable bias could result from region-specific, time-varying correlations between pollution and output induced by production decisions, industrial policies, or regulations.[2] These could bias OLS estimates upward or downward depending on whether low-productivity regions adopt cleaner or dirtier technologies than high-productivity regions over time in response to these actions.

Previous papers in this literature maintain exogeneity by using a short time period and focusing on one or a few firms which do not materially impact overall pollution levels. Estimating with a national sample over a longer period no longer affords this. To overcome the simultaneity and omitted variables biases while achieving comprehensive estimates we employ the number of days with thermal inversions in geographic areas (roughly counties) to instrument pollution. Thermal inversions form due to exogenous meteorological factors yet trap pollutants such as $PM_{2.5}$ near the ground degrading air quality. Previous papers using thermal inversions as an instrument include Arceo *et al.* (2016), Hicks *et al.* (2016), Jans *et al.* (2018), Sager (2019), Chen *et al.* (2017), and Dechezleprêtre *et al.* (2018). The instrument is highly predictive and, when applied, reveals more negative productivity effects than OLS estimates.

---

[2] Our specification includes firm fixed effects ruling out time-invariant sources of bias.

A second estimation obstacle is potential spatial sorting across regions of low- versus high-skilled workers or low- versus high-polluting firms in response to pollution. Using OECD (2011)'s criteria, we classify firms by technology intensiveness and find that pollution is not predictive of the year-by-year fraction of employment in low- versus high-technology firms across locations suggesting that the migration of workers is limited in the short run. Few firms move during the sample period consistent with no significant sorting by extant firms. Excluding the few firms that relocate results in greater effects on productivity indicating that pollution's effect may be even greater if these are representative of the full sample. Pollution is not predictive of firm entry or exit suggesting that endogenous entry and exit choices and survival bias have limited effect on our estimates.

Estimating output's effect on $PM_{2.5}$ concentrations also raises endogeneity issues. Most directly, pollution deters production which will bias OLS estimates. Estimates are also affected by all the same simultaneity and omitted-variable biases as the estimates for pollution's effect on productivity. Using China's joining the WTO to instrument for regional output addresses this because WTO accession is orthogonal to these firm and worker decisions.

This paper makes three primary contributions. First, we provide nearly exhaustive measures for the causal effect of pollution on the short-run productivity of a country's manufacturing sector. Previous studies examine only small sets of workers in particular occupations or a small set of firms. An exception is a subsequent paper by Dechezleprêtre *et al.* (2018) that examines effects of $PM_{2.5}$ on GDP and population across European regions (roughly counties) using aggregated data. Cost-benefit analyses of national environmental policies require comprehensive estimates since effects on particular occupations, firms, or industries may be idiosyncratic. We provide such a nationwide estimate for China and find larger estimates than previous, more focused studies. A possible reason is that we estimate annual cumulative effects rather than those of shorter duration; however, this may also relate to the scope of our estimates. They reflect all manufacturing industries, firms, and occupations rather than specific settings and they capture all channels by which productivity is affected including per-hour productivity and working hours. Our methodology is general and could be applied to any country experiencing sufficient variation in thermal inversions.

Second, we provide general-equilibrium estimates of pollution's effect on output including effects on both productivity and labor supply. Previous papers avoided this complication because they considered only small sets of workers or firms so that it was unnecessary to consider the effect of output on pollution. This also distinguishes our work from Dechezleprêtre *et al.* (2018) which examines only partial-equilibrium effects. We do so by simulating these effects in a dynamic, general-equilibrium model of China's economy. Calibrating the model to observed economic values, we find the general-equilibrium exceed the partial-equilibrium

effects. We believe ours is the first paper to provide general-equilibrium estimates relating productivity and air pollution. The simulation approach is general and can be applied to evaluate policy counterfactuals in any setting in which partial-equilibrium estimates of pollution's effect on output and output's effect on pollution are available.

Third, there is relatively little evidence concerning pollution's effect on high-skilled workers (exceptions are Archsmith *et al.* (2018) on umpires, Heyes *et al.* (2016a) on investors, Heyes *et al.* (2016b) on politicians, and Kahn and Li (2019) on judges). We estimate the effects of $PM_{2.5}$ on productivity separately for firms in high- and low-technology industries and find significant effects for both. This suggests that the results apply not just to older, traditional manufacturing firms but also to those employing newer, more advanced technologies.

Estimates for China are important in and of themselves. China is the world's most populous country and a large source of manufacturing and the resultant pollution. China represented 22% of the world's manufacturing output in 2012.[3] The findings also have implications for the global economy as China incurs a disproportionate fraction of the world's pollution because of its substantial exports. Depending on the type of pollutant, 17 to 36% of China's air pollution is attributable to exports (Lin *et al.*, 2014). Our estimates imply that policies that reduce China's air pollution can generate substantial increases in productivity in addition to health benefits and, given China's extensive exports, benefit other countries via trade. Our estimates complement the literature that estimates the social costs of reduced health due to China's air pollution (Matus *et al.*, 2012; Chen *et al.*, 2013; Ebenstein *et al.*, 2015; Bombardini and Li, 2020; Ebenstein *et al.*, 2016; He *et al.*, 2016; Ito and Zhang, 2020).

Many developing countries are hesitant to implement measures to reduce air pollution for fear of hindering growth (Hanna and Oliva, 2015). Figure 1 illustrates the environmental pollution resulting from China's development. It plots the average concentration of $PM_{2.5}$ across all regions of China over the sample period against annual value added for all firms in our sample. The rapid output increase has resulted in accompanying rapid air pollution increases, especially after China joins the WTO in 2001. Our finding of significant productivity gains from reducing pollution provides additional impetus to implement pollution control measures. Because of China's severe pollution, the central government has designed many policies to reduce air pollution but these have often gone unenforced or under-enforced because local governments lack incentives to do so or their incentives emphasize alternative goals such as economic growth (Li and Zhou, 2005; Chen *et al.*, 2016; Jia, 2017). Our findings suggest local governments may underestimate the benefits to local economic growth of reducing air pollution.

[Insert Figure 1 here.]

[3] "China has a Dominant Share of World Manufacturing," United Nations and MAPI, January 6, 2014 (https://www.mapi.net/blog/2014/01/china-has-dominant-share-world-manufacturing).

The rest of the paper is organized as follows. The next section discusses related literature in the context of a motivating model. Section 3 describes the data; Section 4 specifies the econometric models and discusses identification issues and strategies. Section 5 presents our partial-equilibrium results and Section 6 the general-equilibrium analysis. Section 7 concludes.

2. Pollution, output, and productivity

Air pollution affects a firm's short-run output through its effect on health of workers and their families. An extensive literature documents the negative effects that a high concentration of air pollution can have on human health. According to the Environmental Protection Agency (EPA), short-run exposure can lead to decreased lung function, irregular heartbeat, increased respiratory problems, nonfatal heart attacks, and angina.[4] These short-run effects can result in decreased physical stamina at work and missed work days. Long-run exposure may lead to cardiopulmonary diseases, respiratory infections, lung cancer (EPA, 2004), and asthma (Neidell, 2004). These long-run health problems can manifest themselves in the short run if high levels of pollution trigger conditions resulting from previously accumulated exposure. Infant and elderly morbidity resulting from air pollution (Chay and Greenstone, 2003; Deryugina *et al.*, 2018) can require working adults to miss work to care for them (Hanna and Oliva, 2015; Aragón *et al.*, 2017). Long-term exposure can also reduce life expectancy (Chen *et al.*, 2013; Ebenstein *et al.*, 2017) which can result in experienced workers being replaced by new, inexperienced ones.

Air pollution can also lower cognitive ability, alter emotions, increase anxiety, and have other negative psychological effects (Levinson, 2012; Lavy *et al.*, 2014; Pun *et al.*, 2017; Chen *et al.*, 2018) which would affect the performance of both physical and knowledge workers. All of these effects can be compounded by spillovers to other workers (Arnott *et al.*, 2005, Chapter 4). Moreover, $PM_{2.5}$ can seep into buildings (Thatcher and Layton, 1995; Vette *et al.*, 2001), making avoidance behavior costly or impossible for workers unless their employer provides proper filtration equipment. While our estimates are unable to distinguish between these various channels they capture all of them.

Pollution can affect output through productivity, the intensive margin, and labor supply, the extensive margin. The intensive and extensive margins depend on the context and the time unit measured. In our context, time is measured in worker-years. Therefore, our productivity estimates capture all possible channels that affect per-hour productivity (intensive margin) and hours worked (one type of extensive margin) although we cannot distinguish them. We separately estimate the labor supply effects on number of worker-years (another type of extensive margin). Pollution can also affect capital productivity through firms investing in pollution-

reduction measures, either in response to regulation or to offset decreases in productivity that arise from pollution.

To illustrate this, consider a constant-returns-to-scale, Cobb-Douglas production function in capital (K) and labor (L) in which the PM$_{2.5}$ pollution concentration (Ω) affects capital productivity (A_K), labor productivity (A_L), and labor supply (we assume here and later confirm that pollution does not affect capital supply):

$$Q = [A_K(\Omega)K]^{\gamma}[A_L(\Omega)L(\Omega)]^{1-\gamma}, (1)$$

where γ is the elasticity of output with respect to capital. Logging both sides:

$$ln[Q] = \left[\gamma ln[A_K(\Omega)] + (1-\gamma)ln[A_L(\Omega)]\right] + \gamma ln[K] + (1-\gamma)ln[L(\Omega)]. (2)$$

The first term in brackets on the right-hand side is also total factor productivity: $TFP = \left[\gamma ln[A_K(\Omega)] + (1-\gamma)ln[A_L(\Omega)]\right]$. The effects of pollution are given by:

$$\frac{dln[Q]}{dln[\Omega]} = \left[\gamma \frac{dln[A_K]}{dln[\Omega]} + (1-\gamma)\frac{dln[A_L]}{dln[\Omega]}\right] + (1-\gamma)\frac{dln[L]}{dln[\Omega]}. (3)$$

There are two potential effects: the effect on productivity (the first term in brackets on the right-hand side) and the effect on labor supply. We estimate these two separately. For productivity, we use two different approaches following Syverson (2011): the effect on output per worker and the effect on TFP.

How do these partial-equilibrium effects (general-equilibrium effects are not previously considered) compare to those previously estimated in the literature? In our setting L is measured in worker-years and Q annually. Suppose per-hour labor productivity is a and each worker's annual hours is H then $A_L = a * H$. In the data we observe L but not a or H. Our productivity estimates (both TFP and output per worker) hold the number of worker-years constant so that:

$$\frac{d[TFP]}{dln[\Omega]} = \frac{dln[Q/L]}{dln[\Omega]}\bigg|_L = \gamma \frac{dln[A_K]}{dln[\Omega]} + (1-\gamma)\left[\frac{dln[a]}{dln[\Omega]} * H + a * \frac{dln[H]}{dln[\Omega]}\right]. (4)$$

Our estimates therefore capture both the intensive (per-hour productivity) and one type of extensive margin (hours worked) effects on productivity. We also separately estimate the effect on labor supply (L) (another extensive margin) to determine the effects on total output given by Equation (3).

Extant studies of pollution and productivity observe worker hours (H) and therefore measure effects on per-hour productivity ($dln(a)/dln(\Omega)$); many also separately estimate effects on hours worked ($dln(H)/dln(\Omega)$) but find little effect. PM$_{2.5}$ reduces per-hour productivity of pear-packing workers in California but has little effect on hours worked (Chang et $al.$, 2016). PM$_{2.5}$ also reduces per-hour productivity of garment factory workers in India with no effect on absences (Adhvaryu et $al.$, 2019). PM$_{2.5}$ and SO$_2$ reduce per-hour output of textile workers at two sites in China but has little effect on hours worked (He et $al.$, 2019). Ozone reduces per-hour productivity of outdoor fruit pickers in California but not hours worked (Graff Zivin

and Neidell, 2012) and pollution measured by the air pollution index (API) affects call center workers (Chang *et al.*, 2019) with no effect on hours worked.

To provide precise measures of daily output, all of these previous studies focus on a small group of firms or a particular type of worker. Although this helps establish a causal link because pollution is exogenous to the activities of a small number of firms, the results may not generalize. A few other papers examine pollution's effect on performance in other environments. Air pollution increases students' absences (Currie *et al.*, 2009) and reduces their cognitive performances and test scores (Ebenstein *et al.*, 2016). It also has negative effects on short-run performance of outdoor athletic participants including soccer players (Lichter *et al.*, 2017) and marathon runners (Guo and Fu, 2019).

The previous literature considers only partial-equilibrium effects of pollution on output consistent with their focus on a single industry or firm. To simulate nationwide, general-equilibrium effects we supplement the production function with a pollution-damage function. We assume that $PM_{2.5}$ is created only by the manufacturing sector and specify (where t indexes years in the simulation):[5]

$$\Omega_t = B[\lambda_t Q_t]^{\mu_t}, \text{ (5)}$$

where λ_t is the fraction of national output produced by the manufacturing sector in year t, μ_t is the elasticity of pollution with respect to manufacturing output in year t, and B is the baseline $PM_{2.5}$ concentration across all years.

For our general-equilibrium simulations, in Equation (1) we set $A_{Kt}(\Omega_t) = \Omega_t^{\theta_K} A_{1t}$, $A_{Lt}(\Omega_t) = \Omega_t^{\theta_L} A_{2t}$, and $L(\Omega_t) = \Omega_t^{\kappa/(1-\gamma)} L_t$ (pollution determines effectiveness of each unit of labor):

$$Q_t = \Omega_t^{\theta} A_t K_t^{\gamma} [L(\Omega_t)]^{1-\gamma}, \text{ (6)}$$

where $\theta = \gamma\theta_K + (1-\gamma)\theta_L$ and $A_t = A_{1t}^{\gamma} A_{2t}^{1-\gamma}$. Total-factor productivity in year t is $\Omega_t^{\theta} A_t$. θ is the partial-equilibrium effect of pollution on output holding labor supply constant while κ is the partial-equilibrium effect of pollution on labor supply.

Using estimates of the parameters θ, κ, and μ we simulate a dynamic IAM calibrated to data on China's economy to obtain economy-wide general-equilibrium effects (see Section 6 for details).

3. Primary data

We estimate firm-level productivity combining comprehensive data on firm characteristics with air pollution data for highly-specific geographic areas across all of China from 1998 to 2007. While several different pollutants' effects on

---

[5] The services sector produces little $PM_{2.5}$. Our manufacturing data does not include power plants so we implicitly assume that $PM_{2.5}$ from power plants scales proportionally with manufacturing output.

productivity have been studied we focus on PM$_{2.5}$ because of its severe effects. Our pollution measure is monthly concentration of PM$_{2.5}$ derived from satellite-based Aerosol Optical Depth (AOD) retrieval techniques maintained by the National Aeronautics and Space Administration (NASA).[6] We use the AOD data because it provides the most comprehensive measure of air pollution across China's geography and over time. AOD measures the extinction of the solar beam by dust and haze and can be used to predict pollution even in areas lacking ground-based monitoring stations (Gupta *et al.*, 2006; van Donkelaar *et al.*, 2010; Kumar *et al.*, 2011). Chen *et al.* (2017) validate the AOD data using ground-based, station data in China and find that the difference between them is statistically insignificant conditional on geographic and year fixed effects. The PM$_{2.5}$ concentrations are calculated following Buchard *et al.* (2016).

The AOD data have several advantages compared to ground-based pollution data. First, it predates the beginning of our firm sample in 1998 while ground-based pollution data are available beginning only in 2000 giving us two more years of data. Second, it covers the whole country while ground-based pollution data cover only 42 cities in 2000 increasing to 113 in 2010. Third, ground-based pollution data are potentially subject to human manipulation (Andrews, 2008; Ghanem and Zhang, 2014) while the satellite data are not. The AOD pollution data are reported in grids of 50 by 60 kilometers which we aggregate to the county level – the smallest administrative unit in China to which we can match firm locations.[7] We then average by year to obtain annual mean concentrations of PM$_{2.5}$ in each county-year.

Although the AOD data is remarkably accurate in measuring ground-level PM$_{2.5}$ our paper faces a problem present in much of the literature: different pollutants are highly correlated which may prevent us from isolating a single pollutant's effects. We are potentially aided by the fact that we instrument using thermal inversions and not all pollutants are affected by them. Nonetheless, thermal inversions do affect other pollutants (*e.g.*, carbon monoxide as described by Arceo *et al.* (2016)) and inversions may therefore not be specifically correlated with PM$_{2.5}$ vis-à-vis other pollutants. Therefore, our estimates can be interpreted as air pollution impacts more broadly not necessarily specifically from PM$_{2.5}$.

---

[6] The AOD data are obtained from the Modern-Era Retrospective Analysis for Research and Applications version 2 (MERRA-2) and are available at https://disc.gsfc.nasa.gov/datasets/M2TMNXAER_V5.12.4/summary?keywords=Aerosols#. We utilize M2TMNXAER version 5.12.4 which reports monthly AOD data within each 0.5 degrees latitude by 0.625 degrees longitude (corresponding to 50 by 60 kilometers) grid.

[7] The six-digit administrative code is published by the NBS' Administrative Division: http://www.stats.gov.cn/tjsj/tjbz/xzqhdm/201401/t20140116_501070.html (in Chinese). In constructing the pollution and thermal inversion measures based on the satellite data, we take spatially-weighted averages across a county of all pixels based on the proportion of the county that each pixel represents. Specifically, we interpolate within the original 50- by 60-kilometer grids using the bilinear method (Hijmans *et al.*, 2015) to obtain 10- by 12-kilometer grids to better accommodate counties that are smaller than 50 by 60 kilometers. For counties that span more than one 10- by 12-kilometer grid we use a weighted-average (by area) across all grids that it spans.

Since the satellite pollution measure covers the entire country we can include all manufacturing firms for which we have data. Our firm-level output and characteristics data is from annual surveys of manufacturing firms conducted by China's National Bureau of Statistics (NBS). The survey includes all state-owned enterprises (SOEs) regardless of size and all non-SOEs whose annual sales exceed CNY 5 million (USD 0.8 million) and contains detailed information on firm location,[8] accounting measures, and firm characteristics. This captures 90.7% of China's total manufacturing output in the later years (Brandt *et al.*, 2012). During our sample period this includes 2,082,823 firm-year observations and 544,308 unique firms.

Following Brandt *et al.* (2012) we match firms over time to form an unbalanced panel.[9] This matching process is careful and avoids interpreting name changes as different firms (Brand *et al.* (2012), Section A.2 of their online appendix). The panel is very unbalanced due to China's rapid growth during this period which leads to a large number of new firms surpassing the CNY 5 million revenue threshold year-by-year.[10] We also follow Brandt *et al.* (2012) in converting nominal into real values using industry-level price indices. We drop observations with missing or unreliable data following the previous literature (Cai and Liu, 2009; Brandt *et al.*, 2012; Yu, 2015).[11] These represent 10.3% of observations and 7.9% of total manufacturing output. The biggest loss of data in estimation is due to firms appearing in only one year and dropped with the inclusion of firm fixed effects. These represent 16.1% of observations and 30.5% of total manufacturing output.[12]

Finally, we winsorize the top and bottom 0.5% of data based on each of the values of output, value added, employment, and capital to be consistent with the previous literature (Cai and Liu, 2009) and because of the risk that these involve data entry or reporting errors. However, we show that the results are similar using the non-winsorized data. The results are also robust to excluding the few multi-plant firms in the data which cannot be uniquely matched to a single location. The final data

---

[8] Firm location is known at least up to the six-digit administrative code level used to match to the pollution data. Specific addresses are known only for a small share of firms and thus using these to match would make our data far less comprehensive.

[9] Their Stata programs are posted at: http://feb.kuleuven.be/public/N07057/CHINA/appendix.

[10] Brandt *et al.* (2012) confirm that these appearances are *de novo* and not due to firm restructuring. The annual rate of exit is less than 14% (Section A.2 of their online appendix).

[11] We drop observations with missing or negative values for output, value added, employment, or capital; firms with fewer than eight employees since they may not have reliable accounting systems; and firms violating accounting identities such as the components of net assets exceeding total assets or current depreciation exceeding cumulative depreciation.

[12] Because of China's rapid growth during this time, 43% of these single-year firms occur in the last sample year. For the remaining 57% that occur earlier, 8% are SOEs and therefore must be due to actual entry and exit. For the remaining 92%, we do not know whether they appear in only a single year because they enter and then exit or they move above and then below the CNY 5 million threshold. However, as Online Appendix 1 shows, the characteristics of these firms are similar to the full sample except that they are smaller. Given the large number of single-year firms, we comment more below on the potential effects of censoring due to the CNY 5 million threshold.

include 1,593,247 firm-year observations for 356,179 unique firms. Geographically, the sample includes 2,755 counties with an average of 58 firms per county-year.

One issue with obtaining broad-based measures of productivity is measuring it. Previous papers in the literature focused on one or a small set of firms producing a single well-defined product where output quantity is directly measurable. Pooling all manufacturing firms, as we do, requires an alternative measure. Since we abstract from intermediate inputs we use value added as the measure of output. Value added is reported directly in the data and equals total production (including both sales and inventory) of all goods produced in the year valued at their market prices less the cost of all intermediate inputs employed in producing them. Value added per worker is commonly used as a measure of productivity in the general-productivity literature (Syverson, 2011; Brandt *et al.*, 2012) and in the temperature-productivity literature (Hsiang, 2010; Dell *et al.*, 2012). However, it raises two issues.

First, using value added requires that prices do not reflect market power in either the primary or downstream input markets. If they do not, monetary-based measures are preferred over quantity-based as they reflect quality differences (Syverson, 2011). As with other studies that use data sets with many firms, we cannot guarantee that prices are independent of market power; however, thermal inversions are independent of firm-level market power allowing us to consistently estimate pollution's effect on productivity via instrumented values. The second issue concerns multi-product firms. Their product mix is not discernible from the firm's value added and may be correlated with pollution levels. However, our instrumenting strategy addresses this: thermal inversions are uncorrelated with a firm's decision of product mix thereby removing any bias.

We obtain daily, station-level weather variables that could affect both air pollution and productivity including temperature, precipitation, relative humidity, wind speed, sunshine duration, and barometric pressure from the National Meteorological Information Center of China. We convert the daily station data to daily-county level using the inverse-distance weighting method (Deschênes and Greenstone, 2011) to give less weight to stations more distant from the geographic centroid. To allow for extreme weather events to have differential effects from more normal ones, we follow Deschênes *et al.* (2017) and calculate twenty quantiles for each weather variable based on the daily distribution and include the annual number of days within each quantile. The weather measures are then matched to the firm data by county-year.

For our instrument, we obtain thermal inversion data from NASA.[13] The data report air temperatures every six hours at 42 vertical layers from 110 meters to 36 thousand meters within 50- by 60-kilometer grids. We aggregate from the grid to the county

---

[13] Specifically, we use product M2I6NPANA version 5.12.4 from MERRA-2 available at https://disc.sci.gsfc.nasa.gov/datasets/M2I6NPANA_V5.12.4/summary?keywords=%22MERRA-2%22%20M2I6NPANA&start=1920-01-01&end=2017-01-16.

level within each six-hour period and for each layer. Following Arceo *et al.* (2016), we define a thermal inversion as the temperature of the second layer (320 meters) being higher than that of the first layer (110 meters).[14] We determine this within each six-hour period of each day for each county. Since thermal inversions are short-lived (on the order of a few weeks) relative to the annual output measure, we use a cumulate annual measure of inversions to make them temporally consistent. For each county, we use the annual number of days that have at least one inversion.

Table 1 presents summary statistics of the key variables. The firm characteristics are at the firm-year level and reflect a high degree of variation in productivity. The pollution and thermal inversion data are at the county-year level. The pollution levels are such that they are likely to have an effect on mental and physical health and therefore productivity. The World Health Organization (WHO) recommends a maximum annual mean of ten $\mu g/m^3$ for $PM_{2.5}$ and a maximum mean of twenty $\mu g/m^3$ within a 24-hour period (WHO, 2006). In the sample, the mean annual $PM_{2.5}$ level is 53.5 with a high of 134.8. The annual number of days with thermal inversions displays significant variation ranging from zero to 333 days per year with a mean equal to a little under one-half year.

[Insert Table 1 here.]

4. Partial-equilibrium model specification and identification

To estimate the general-equilibrium effects of pollution on output we proceed in three steps. We first estimate the partial-equilibrium effects of pollution on output by parameterizing the model in Section 2. Second, we parameterize the pollution-damage function specified in Section 2 and estimate the partial-equilibrium effects of output on pollution. Third, we combine these two partial-equilibrium estimates in an IAM and simulate the general-equilibrium effects. This section discusses the specification and identification of the partial-equilibrium estimates.

4.1 Partial-equilibrium effect of pollution on productivity

To estimate the effect of pollution on productivity holding labor supply constant, we model total factor productivity in Equation (6) in a log-linear form to be consistent with the previous literature that uses this functional form to relate productivity to physical pollution concentrations:

$$ln[Productivity_{it}] = \beta_0 + \beta_1\Omega_{it} + \beta_2 W_{it} + \alpha_i + \rho_t + \varepsilon_{it}, (7)$$

where i denotes firms and the pollution elasticity $\theta = \beta_1\overline{\Omega}$ where $\overline{\Omega}$ is mean $PM_{2.5}$ across all regions.[15] W contains the vector of weather variables faced by firm i in

---

[14] The latitude used is referenced to sea level. There are missing values if layers are below the latitude for that grid. For example, if a grid's latitude is 400 meters the first and second layers (110 and 320 meters) will be missing. In these cases, we use the two closest non-missing layers.
[15] As we show, estimation is robust to using the log-log form.

year t. We aggregate the annual pollution and weather measures to the county level because the location of most firms is known only at the county level and not finer. Because of this, we check the robustness to clustering the standard errors at the county-year level. θ captures the effect of pollution on productivity holding labor supply constant.

Firm fixed effects (α_i) capture time-persistent firm attributes that affect productivity. Since very few firms switch counties (7%) over the sample period, these also absorb most county-specific time-invariant factors that affect productivity. Similarly, no firms switch industries so that all time-invariant, industry-specific unobservables affecting productivity are absorbed by the firm fixed effects. Year fixed effects (ρ_t) capture annual national shocks to firm output such as business cycle effects. The error term (ε_{it}) captures time-varying, firm-specific unobservables that affect productivity. In our baseline estimation we cluster standard errors by firm to allow for serial correlation in productivity within firm over time but we show robustness to other clustering patterns.

We use two different measures for productivity: output per worker $ln(Y_{it}/L_{it})$ where Y is value added and L is number of workers and total factor productivity TFP_{it} for firm i in year t.[16] In estimating TFP, we instrument for firms' endogenous choices of inputs using two different approaches: investment as an instrument (Olley and Pakes, 1996) and intermediate inputs as an instrument (Levinsohn and Petrin, 2003). Table 1 provides the summary statistics for TFP estimated under both approaches. The correlation between TFP (using the OP method) and output per worker is 0.71, significant at better than the 0.01% level. We use output per worker for our primary results to be consistent with the environmental economics literature but the results are robust, although with somewhat smaller effects, using TFP. For TFP, we use a two-step approach as in Wang and Wang (2015), Yu (2015), and Brandt *et al.* (2017): in the first step we estimate TFP and in the second step relate TFP to pollution including controls.

Identification requires that, conditional on the control variables, pollution is independent of the error in Equation (7). The causal identification issues that are specific to our context include simultaneity bias, omitted variable bias, and spatial sorting. We discuss these issues before introducing the pollution-damage function.

4.2 Causal identification issue – simultaneity and omitted variable biases

Simultaneity bias can lead OLS estimates of pollution's effect on productivity to be biased either upward or downward. Absent any effect of pollution on productivity, higher productivity in a county leads to both more output and more pollution, biasing them upward toward or above zero. On the other hand, if pollution

---

[16] Estimating output per worker has been criticized because it depends on the level of capital employed (Syverson, 2011). This is not a problem in our setting because our instrumented pollution measure is orthogonal to inputs.

decreases productivity this will lower output and therefore pollution biasing OLS estimates downward away from zero. If pollution lowers productivity, firms may also compensate by using more of alternative inputs. If these inputs are high-polluting this would bias OLS estimates downward while compensation to clean inputs would bias them upward.

Omitted-variable bias due to local, time-varying conditions could also lead to either an over- or under-statement of pollution's effect on productivity in OLS estimates (firm fixed effects capture time-invariant conditions). For example, counties with more productive firms may implement more advanced, lower-polluting technology over time leading to an upward bias. Alternatively, firms that have older, higher-polluting technology may have low productivity and insufficient funds to upgrade their production technology over time leading to a downward bias as technology degrades. Local trends in regulatory conditions may also bias OLS estimates. For example, counties with high-productivity workers may impose more stringent environmental regulations over time leading to a downward bias. On the other hand, an upward bias could result if counties with older, less productive and higher polluting technologies face environmental "crises" and initiate more stringent regulations. We address these identification issues using instrumental variables.

A valid instrument is correlated with a county's air pollution but uncorrelated with its resident firms' productivity except via pollution. Our instrument is the annual number of days with at least one thermal inversion for each county. Normally, air temperature decreases with altitude above the Earth's surface. A thermal (or temperature) inversion is a deviation from this. It occurs when a mass of warmer, less dense air moves above a cooler, denser air mass trapping dust and pollutants near the ground and increasing air pollution. Since thermal inversions are a meteorological phenomenon and, after conditioning on weather variables, unrelated to production except via pollution, it is a valid instrument. A few studies have applied this identification strategy to estimate the effects of air pollution on various outcomes (Arceo *et al.*, 2016; Hicks *et al.*, 2016; Jans *et al.*, 2018; Sager, 2019; Chen *et al.*, 2017; Dechezleprêtre *et al.*, 2018). A caveat to this approach is that inversions can affect the efficacy of pesticides and fertilizer in agriculture. Although our data does not include agriculture, there could be knock-on effects upstream or downstream in manufacturing that could affect the instrument's exogeneity.

With this as our instrument we employ two-stage least squares (2SLS) with the first-stage equation:

$$\Omega_{it} = \tau_0 + \tau_1 I_{it} + \tau_2 W_{it} + \alpha_i + \rho_t + \epsilon_{it}, \quad (8)$$

where I_{it} is the number of thermal inversion days in firm i's county in year t. The weather controls from the second stage are included because these same variables affect the formation of inversions (Arceo *et al.*, 2016) and are also needed to ensure the exclusion restriction is met in the second stage.

4.3 Causal identification issue – spatial sorting

Spatial sorting results from either firms or workers self-selecting into particular counties based on their pollution levels. Firms may choose to locate in counties with less severe pollution because it leads to higher productivity which would bias estimates of pollution's effect on productivity upward toward or above zero. Alternatively, firms may choose to locate in counties with more severe pollution because it reflects less stringent local environmental regulations and therefore lower costs – the "pollution haven" effect (Becker and Henderson, 2000; Greenstone, 2002; Brunnermeier and Levinson, 2004). In this case, the direction of the bias induced depends on whether firms with higher pollution output are more or less productive.

Firm fixed effects absorb any initial endogenous sorting of firms across counties so that only sorting that occurs during the sample period will introduce bias.[17] Only 7% of firms relocate counties during the sample period. Excluding these from estimation suggests some sorting effects and larger productivity effects absent sorting. Firm entry and exit during the sample period could introduce bias through endogenous selection. To check for this, we estimate the effect of pollution on the fraction of firms exiting and entering each county in each year (controlling for endogeneity) and find no significant effect for either.

A second possible type of spatial sorting is workers choosing their location based on their willingness to pay for air quality. High-skilled workers generally have a higher willingness-to-pay for better air quality and are more productive than low-skilled workers. This would result in dirty cities having a high proportion of low-skilled workers and low firm productivity and clean cities having a high proportion of high-skilled workers and high firm productivity (Lin, 2017) exacerbating pollution's negative effect on firm productivity.

Firm fixed effects absorb any initial endogenous sorting of workers so that only movement of workers during the sample period will create bias. This effect is not likely large since we estimate annual effects and such migration would likely occur over longer periods,[18] but we check for evidence of this occurring. Based on OECD (2011) we categorize each firm as high, medium-high, medium-low, and low technology and, based on their employment, compute the fraction of workers in each of the four categories in each county-year. Changes in pollution (controlling for endogeneity) is not predictive of changes in these fractions over time except for a small, positive effect on the low-technology fraction.

4.4 Partial-equilibrium effect of output on pollution

To estimate the effect of output on pollution (μ), we take logs and parameterize Equation (5):

---

[17] Sorting could occur by industry but as no firms switch industries firm fixed effects absorb this.

[18] Chen *et al.* (2017) find that people migrate in response to air pollution over a five-year period.

$$ln[\Omega_{ct}] = \psi_0 + \mu ln[Q_{ct}] + \alpha_c + \rho_t + \omega_{ct}, \text{ (9)}$$

where c indexes counties, Ω_{ct} is pollution concentration in county c in year t, and Q_{ct} is total output in county c in year t. County fixed effects (α_c) capture baseline concentrations in each county and year fixed effects (ρ_t) capture aggregate annual changes in concentrations. We assume μ is constant over our sample period but vary it outside that in our general-equilibrium simulations.

To instrument for the endogeneity of output with respect to pollution, we take advantage of China joining the WTO in late 2001 as an exogenous shock to output for firms in China's coastal regions relative to that in its inner regions. This approach of comparing high-and low-exposure regions before and after trade liberalization shocks has been widely used in the trade literature (*e.g.*, Goldberg and Pavcnik, 2005; Verhoogen, 2008; Topalova, 2010). This provides a differences-in-differences estimator with counties in coastal regions as a treatment group and those in inner regions as a control group. With this as an instrument, we employ 2SLS with first-stage equation:

$$ln[Q_{ct}] = \varsigma_0 + \varsigma_1 I_{t>2001} I_{c \in Coast} + \alpha_c + \rho_t + \nu_{ct}, \text{ (10)}$$

where $I_{t>2001}$ is an indicator variable set to one in years after 2001 and zero otherwise and $I_{c \in Coast}$ is an indicator variable set to one if the county is on the coast and zero otherwise.

5. Partial-equilibrium results

5.1 Effect of pollution on productivity

We first present estimates not accounting for any endogeneity bias between productivity and pollution. Table 2 presents OLS estimates of Equation (7) using output per worker. Without weather controls (Column (1)), PM2.5 pollution has no effect on productivity. Including weather controls (Column (2)), reveals a positive effect of pollution on productivity.

[Insert Table 2 here.]

In the presence of simultaneity or omitted-variable biases, OLS produces inconsistent estimates. We use Equation (8) to produce instrumented values of pollution concentrations. We first check whether thermal inversions are predictive of productivity in a reduced-form estimate. Columns (3) and (4) of Table 2 show the results without and with weather controls. Both yield statistically significant results and the coefficient with weather controls implies that one additional day with an inversion annually decreases productivity by 0.03%.

The top panel of Columns (5) and (6) of Table 2 show that the instrument is a powerful predictor of PM2.5 concentrations. The coefficient on annual days with thermal inversions is positive and highly significant both with and without weather

controls and the Kleibergen-Paap Wald rk F-statistic (KP) (Kleibergen and Paap, 2006) for weak identification is much larger than the Stock-Yogo critical value of 16.38.[19] One additional inversion day increases $PM_{2.5}$ by 0.036 $\mu g / m^3$ controlling for weather. This is a big effect. Using the results with weather controls, a one standard deviation increase in the annual number of days with inversions increases $PM_{2.5}$ by 2.8 $\mu g / m^3$ (5.3%).

The lower panel of Columns (5) and (6) show the second-stage results. Consistent with the instrument correcting for endogeneity, the coefficient moves to being significantly negative. Without weather controls, instrumented $PM_{2.5}$ has a negative and very significant effect on output per worker. A one $\mu g / m^3$ increase in $PM_{2.5}$ decreases productivity by 0.80%. Controlling for weather increases the estimate slightly and makes it even more significant. A one $\mu g / m^3$ increase in $PM_{2.5}$ decreases productivity by 0.82%. Evaluating this at the mean $PM_{2.5}$ in the sample (53.5) yields an elasticity of -0.44. Dechezleprêtre *et al.* (2018) find a lower elasticity (-0.11) for European regions which could be due either to lower levels of pollution in Europe or due to their data including both manufacturing and services. Using TFP as our productivity measure yields slightly lower estimates: an elasticity of -0.26 using the OP estimator and -0.19 using the LP estimator (Columns (7) and (8)). Throughout the rest of the paper we focus on results using output per worker since previous papers estimating pollution's effect have used this. However, the results are robust to, but somewhat lower, using TFP. Also, since controlling for weather is preferred we do so throughout the remainder of the paper.

How large are these effects? Consider a nationwide exogenous decrease in $PM_{2.5}$ of 1%. This could include reducing other pollution sources like road dust, automobile exhaust, and power generation or by decreasing pollution per unit of manufacturing output via methods that do not reduce output. The resulting productivity improvement increases the average firm's value added by CNY 56.3 (USD 7.4) thousand annually and increase total value added across all firms by CNY 9.0 (USD 1.2) billion annually. This represents 0.060% of China's GDP.[20] Online Appendix 2 compares estimates for counties in China's three major economic centers (Jing-Jin-Ji, Yangtze River Delta, and Pearl River Delta)[21] to the rest of the country. The estimates for the two are fairly close to each other and significant implying that air pollution affects productivity even outside the major manufacturing centers.

---

[19] Stock and Yogo (2005) critical values apply when model errors are independent and identically distributed. No critical values are available for the case when the model allows for standard errors that are robust to heteroskedasticity and clustering.

[20] A 1% decrease in $PM_{2.5}$ increases annual output by 0.44%. The mean annual output per firm in the sample is CNY 12.82 million implying an annual increase of CNY 56.3 thousand. There is an average of 159,325 firms present in each year of the sample implying an annual increase in output across all firms of CNY 9.0 billion annually. China's average annual real GDP over the ten-year sample period is CNY 14.85 trillion.

[21] The Jing-Jin-Ji region includes Beijing, Tianjin, and Hebei; the Yangtze River Delta region includes Shanghai, Jiangsu, Zhejiang, and Anhui; and the Pearl River Delta region includes Guangdong.

Since our estimates capture pollution's effect on both per-hour productivity and working hours, it is useful to disentangle the two for comparisons to previous estimates of per-hour productivity effects.[22] We borrow estimates from Aragón *et al.* (2017) which finds an elasticity of working hours with respect to $PM_{2.5}$ of -0.21 in Lima, Peru. Assuming $PM_{2.5}$'s effect on working hours is the same in China, our estimated elasticity of per-hour productivity with respect to pollution is -0.23. It is similar to the upper end of estimates by He *et al.* (2019) for textile workers in two firms in two Chinese provinces. They find elasticities ranging from -0.035 to -0.30 from $PM_{2.5}$ exposure if effects are accumulated over 25 to 30 days.

Our estimate exceeds that in Adhvaryu *et al.* (2019), which finds an elasticity of -0.052 for per-hour productivity with respect to $PM_{2.5}$ for garment factory workers in India. It is also larger than the elasticity of -0.062 for $PM_{2.5}$ found in Chang *et al.* (2016) for indoor pear packers in California and the elasticity of -0.023 with respect to the API for services workers (Chang *et al.* (2019)). The fact that we estimate elasticities that are at least as great as or greater than previous papers could be due to two factors. First, previous estimates apply only to particular worker types or small sets of firms. Second, previous studies measure daily or monthly effects while we capture annual cumulative effects.

We can also compare our estimates to studies that estimate the effect of $PM_{2.5}$ on economic outcomes besides productivity. To do so, we normalize results to the monetary impact of a one-percent decrease in $PM_{2.5}$, which in our case increases productivity by USD 1.2 billion annually. Deryugina *et al.* (2018) estimate the short-run effect of $PM_{2.5}$ on mortality in the U.S. They find that a one-percent decrease in $PM_{2.5}$ concentration (0.11 $\mu g/m^3$) leads to a gain of USD 0.45 billion annually in avoided mortality – about one-third of our estimate. Bishop *et al.* (2018) estimate the long-run effect of $PM_{2.5}$ on dementia in the U.S. A one-percent decrease in $PM_{2.5}$ concentration (0.09 $\mu g/m^3$) reduces medical expenditures on dementia by USD 0.11 billion annually, about one-tenth of our estimate. Chen *et al.* (2018) estimate the short-run effect of $PM_{2.5}$ on mental illness in China. A one-percent decrease in $PM_{2.5}$ concentration (0.48 $\mu g/m^3$) reduces expenditure on mental illness treatment by USD 0.60 billion annually – about one-half of our estimate.

5.2 Robustness checks

Online Appendix 3 shows robustness to different assumptions about the model compared to the baseline results replicated in Column (1). Since some of our explanatory variables are grouped at the county-year level and there may be time-invariant unobserved factors affecting productivity at the county level, the standard errors may be biased downward (Kloek, 1981; Moulton, 1986). We check this in several different ways. Column (2) allows for two-way clustering of errors by firm and county-by-year (Cameron *et al.*, 2011). This allows for serial correlation in

---

[22] This makes use of the fact that the elasticity of productivity equals the elasticity of productivity per hour plus the elasticity of hours worked as shown in Equation (4).

productivity within firms as well as spatial correlation within each county-year. The results remain significant. Since there is no standard way to cluster with multi-way clustering (Cameron and Miller, 2015) we try two other methods. Column (3) clusters the standard errors by county-year, which allows unobservables to be spatially correlated within each county-year. The standard errors are similar to those under two-way clustering. Clustering at the county level, which allows for spatial and serial correlation within county, in Column (4), increases standard errors only slightly and the results remain significant.

Our baseline results use year fixed effects to control for nationwide time trends. We test for robustness to regional trends in four different ways: region-by-year fixed effects[23] in Column (5); province-by-year fixed effects in Column (6); province-specific quadratic time trends in Column (7); and year fixed effects along with province-specific quadratic time trends in Column (8). All four yield very significant results and all yield larger point estimates than our baseline except for province-specific quadratic time trends. We continue to use year fixed effects as the baseline because the province-specific time trends impose a specific functional form and the flexible year-by-province fixed effects results are less conservative.

Our baseline estimates weight all observations equally. Column (2) of Online Appendix 4 re-estimates weighting observations by value added per firm. The coefficient yields a slightly higher elasticity (-0.47) than the baseline estimates shown in Column (1). Column (3) shows that not winsorizing the data leads to results very similar to the baseline estimates (elasticity of -0.47 evaluated at the mean $PM_{2.5}$ of 53.3). Column (4) uses the raw data (before eliminating the unreliable observations as described in footnote 11 and without winsorizing) yielding a somewhat greater elasticity (-0.58) using mean $PM_{2.5}$ of 53.3. The survey is at the firm level and therefore it is possible that a firm has multiple plants in different locations leading to an incorrect match with the pollution data. Column (5) eliminates the firms that have multiple plants (5% of our sample). The estimated elasticity (-0.47) is very similar to the baseline based on mean $PM_{2.5}$ of 53.9. Finally, Column (6) uses logarithmic rather than linear pollution. The elasticity (-0.52) is somewhat larger.

As a test of whether it is inversions that are causing the shifts in pollution and therefore productivity, we run a placebo test in which we randomly reassign the pollution to the inversion and weather data across years. We repeat this one hundred times and re-estimate the model. Online Appendix 5 shows the estimates along with 95% confidence intervals. Only four of the one hundred estimates are significantly different than zero and all four barely so.

5.3 Tests for firm sorting

Firms may relocate to places with better air quality to improve productivity or to places with lax environmental regulation to lower costs. Table 3 shows tests for this

---

[23] We divide China into eight regions following Zhang *et al.* (2018).

potential spatial sorting. Column (2) estimates excluding firms that relocated across counties (about 7% of firms) during the sample period. The estimated elasticity (-0.67) based on a mean $PM_{2.5}$ of 53.7 is larger than that of the baseline estimate (-0.44) using all firms (replicated in Column (1)) consistent with either firms avoiding pollution to increase their productivity or a "pollution haven" effect and high-polluting firms being more productive than low-polluting. This also means that our baseline estimates may understate pollution's effect on productivity to the extent that the non-relocating firms are representative of the full sample.

[Insert Table 3 here.]

Although firm fixed effects in our main results control for any initial sorting of firms, new firms that enter during the sample period may choose locations endogenously based on pollution. To see if this might affect the results, Column (3) of Table 3 tests whether a county's instrumented pollution significantly affects the fraction of new firms entering the county in the following year. We aggregate to the county-level for this analysis because we do not observe firms prior to entry and therefore cannot create an entry variable at the firm level. In addition to the weather controls we include county and year fixed effects so that identification derives from within-county variation over time. We cluster standard errors at the county level to allow intertemporal correlation in unobserved factors across years. Year 1998 data is dropped because it is the first year of our sample period and thus we cannot determine the level of entry. The estimated effect of entry is close to zero and insignificant consistent with pollution not affecting firm location choice on entry.

If pollution's effect on productivity is strong enough firms may exit the market. Estimates using the full sample are conditional on survival, potentially understating the productivity effect. To see if this might be a major factor, Column (4) of Table 3 tests whether a county's instrumented pollution significantly affects the fraction of firms exiting the county in the following year. This regression is analogous to the entry regression and includes the same control variables and uses the same clustering of standard errors. Year 2007 data is dropped in this estimation since we cannot observe whether firms present in 2007 exit in 2008. The estimate is close to zero and insignificant suggesting that exit bias is not a major concern.[24] This also suggests that any actions taken by the government to shut down firms in high-polluting areas and induced by thermal inversions are minimal.

We also repeated the entry and exit analyses to see whether there was significant spatial sorting in response to the most important environmental policy that occurred during our sample period. This policy, the Air Pollution Prevention and Control Law 2000 Revision, was officially issued on April 29, 2000. It identified 47 key cities

---

[24] Using a balanced panel could address selection effects due to entry or exit. However, only 7% of firms are present in all years due to China's rapid growth as discussed in Section 3. For this small sample, the estimates are very significant and the estimated elasticities are much greater presumably due to pollution exposure levels that differ from those faced by the full sample.

and imposed stringent environmental regulations on them. We divided the sample into these cities versus all others. The results are shown in Online Appendix 6 and do not reflect any significant effect of pollution on firm entry or exit in the affected or non-affected cities.

Since the sample censors non-SOE firms with less than CNY 5 million in annual revenues ("below-scale" firms), this may confound entry measures. To see if this is so, we simulate the magnitude of censoring required to substantially change the results. Using cross-sectional data available on the full sample of all firms in 2004 when a full manufacturing census was conducted, we calculate each county's "below-scale" and total firms as a fraction of the total number nationwide. We then adjust that county's observed entry rate in each year by assuming that r% of firms that entered nationwide actually moved from "below-" to "above-scale." For each county we weight r by the ratio of the county's fraction of "below-scale" firms relative to fraction of total firms in 2004. This allows the county-level adjustments to be made based on whether they have a disproportionately small or large number of "below-scale" firms relative to other counties in 2004.

For example, suppose that 9% of firms nationwide appeared for the first time in a given year. Consider a county that had 0.04% of the nation's below-scale firms in 2004, 0.05% of the nation's total firms in 2004, and that 8% of its firms appeared for the first time in that year. For r equal to 10% (fraction of firms that appeared nationwide that we assume moved from "below-" to "above-scale" rather than entering), we would adjust this county's entry rate to be 8% - 9%*0.1*(0.0004/0.0005) = .0728. Having adjusted these rates for all years and counties, we re-run the entry regression varying r from 0 to 1 but bounding the entry rate to be non-negative. Online Appendix 7 describes the procedure in more detail and Online Appendix 8 shows the results for increments of 0.1 for r. Instrumented pollution has no significant effect on entry over the entire range of r providing suggestive evidence that censoring does not affect the results.

We modify the exit rate in an analogous manner to test the sensitivity of our exit regression to the censoring of "below-scale" firms. That is, we adjust each county's exit rate in a given year by assuming that r% of firms that exited nationwide actually became "below-scale" rather than exiting. For each county we again weight r by the ratio of the county's fraction of "below-scale" firms relative to fraction of total firms in 2004 bounding the exit rate to be non-negative. The results are shown in Online Appendix 9. The results are again insensitive to the value of r over the entire range – instrumented pollution has no significant effect on exit.

5.4 Tests for worker sorting

It is also possible that workers endogenously select their location based on local air quality. High-skilled workers are more productive and generally have a higher willingness to pay for better air quality. If this leads to significant sorting of worker

skill levels across counties, pollution's effect on productivity is attenuated for firms with high-skilled workers. To test for worker sorting based on pollution levels, we see whether a county's instrumented pollution in a year affects the fraction of the county's workers employed by high- versus low technology firms in that year. We classify a firm's technological intensity based on its industry following OECD (2011), which classifies industries as high, medium-high, medium-low, and low technology. We then compute the fraction of workers employed in each of these categories in each county-year using each firm's employment. In addition to weather controls, we include county and year fixed effects so that the effects are identified by variation within county over time. We cluster standard errors by county to allow for intertemporal correlation of unobservables within each county.

Columns (1) through (4) of Table 4 show the results of estimating how instrumented pollution affects the fraction of employment in each of these four categories. The effects are all insignificant except for the fraction in low-technology industries, which air pollution increases. This is consistent with low-productivity workers sorting to more polluted areas although the effects are small. A one $\mu g/m^3$ increase in $PM_{2.5}$ increases the fraction of employment in low-skilled industries by 0.0033 which is only 0.86% of the average fraction of low-technology employment across counties. To test for the robustness of the technology classifications and make sure that a small number of firms within each category is not an issue, Columns (5) and (6) repeat the estimation combining the two high-technology categories into one category and similarly for the two low-technology categories. Instrumented pollution has no significant effect on the fraction of employment in either category.

[Insert Table 4 here.]

5.5 Effect by worker skill level

We are aware of only four papers that consider the effect of pollution on productivity of high-skilled workers and these focus on specific worker categories: Archsmith *et al.* (2018) on umpires, Heyes *et al.* (2016a) on investors, Heyes *et al.* (2016b) on politicians, and Kahn and Li (2019) on judges. Air pollution is commonly thought to primarily affect outdoor workers because of their unfiltered exposure and their holding more physically-demanding occupations than high-skilled indoor workers. However, $PM_{2.5}$ can permeate indoors making it possible for it to affect indoor workers. Our data allow us to offer some evidence by skill level for manufacturing firms in China. We categorize firms' technological intensity based on the four industry categories in OECD (2011) and estimate the effect of pollution on productivity separately for the sub-sample in each category.

The results are shown in Columns (2) through (5) of Table 5 alongside estimates for the full sample in Column (1). The effects are above those of the full sample for the high-technology firms (elasticity of -0.73) and below for the low-technology firms (elasticity of -0.33). This is consistent with higher-skilled workers employed by more

technologically-intensive firms having a higher marginal effect on productivity than lower-skilled workers so that an equivalent level of pollution diminishes productivity more for high-technology firms. These results also suggest that the previous evidence for specific high-skilled workers extends to manufacturing firms and is consistent with evidence that air pollution affects cognitive not just physical effort. Columns (6) and (7) show that this result holds if only two categories of worker skill levels are used.

[Insert Table 5 here.]

5.6 Effect on labor supply, capital, and output

Estimates so far capture the effect on productivity conditional on the number of workers. Pollution may also affect the number of workers employed (the κ parameter in Equation (6)). To assess this, we estimate Equation (7) with log number of workers in each firm as the dependent variable using annual number of days with a thermal inversion as the instrument. The survey data capture both permanent and contract employment thereby making it likely we can capture annual adjustments in response to pollution. The survey measures end-of-year employment so that employment changes due to pollution over the course of a year are captured.

The results are shown in Column (2) of Table 6. A one $\mu g/m^3$ increase in $PM_{2.5}$ increases employment by 0.51% implying an elasticity of 0.27. Although firms increase employment to compensate for some of the productivity loss, it is not enough to offset the negative productivity effects. Moreover, employing additional workers imposes costs on firms. We can use the average wage in the sample to produce a ballpark estimate of these costs. A one percent increase in $PM_{2.5}$ increases employment by 0.27%, or 0.56 additional workers per firm. The average annual wage per worker in the sample is CNY 12,650 (USD 1,664) implying an additional cost per firm of CNY 7,147 (USD 940). Aggregated across all firms this equals CNY 1.14 billion (USD 0.15 billion) annually or 12.7% of the productivity loss from the 1% increase in $PM_{2.5}$.

[Insert Table 6 here.]

In Column (3) of Table 6, we show the results of estimating Equation (7) with log capital as the dependent variable.[25] There is no significant effect. Column (4) estimates the effect of pollution on log value added. The effect is significant and the elasticity of value added with respect to pollution is -0.17. This equals the summed effect of pollution's effect on productivity ($\theta = -0.44$) and its effect on labor supply ($\kappa = 0.27$) and will also be used below in our general-equilibrium simulation.

---

[25] We calculate capital stock using the perpetual inventory method in Brandt *et al.* (2012).

5.7 Mitigation of pollution-productivity effect

As shown above, firms compensate for the reduced productivity that pollution causes by hiring more labor. It is useful to know whether high-polluting firms compensate more or less than low-polluting firms since this has ramifications for the resulting level of pollution and output. Columns (2) and (3) of Table 7 compare the effect of pollution on labor supply for "polluting" versus "clean" firms.[26] The effects do not differ significantly between the two. Columns (5) and (6) provide one possible explanation for this. "Clean" firms experience a larger negative productivity shock than "dirty" firms. While this would imply a greater incentive for "clean" firms to hire more workers than "dirty" firms, "clean" firms may be more likely to utilize high-skilled labor which is also likely to be in less elastic supply than low-skilled labor.

[Insert Table 7 here.]

Firms may respond to the lower productivity caused by inversions vis-à-vis pollution by adjusting their production processes. To test for this, we run reduced-form estimates relating the number of inversions to productivity distinguishing counties with an above-median number of inversions versus below-median. The results in Online Appendix 10 show that inversions reduce productivity more in areas with fewer inversions consistent with firms in high-exposure regions adjusting their production in response to the level of inversions. This also means that our estimates are inclusive of the effects of this avoidance behavior.

Environmental regulations could result in differential effects on firms in different industries or locations including due to different strategic responses to these regulations (Zou, 2018). However, we are unable to test for this. Prior to 2008, environmental regulation in China was minimal and the policies in place were often unenforced or under-enforced.[27] We suspect prior to this, GDP-based promotion criteria for local government officials led them to emphasize GDP growth to the exclusion of environmental quality. Nonetheless, differential effects will only be reflected in our results to the extent they are correlated with thermal inversions.

5.8 Effect of output on pollution

Estimating output's effect on pollution depends on obtaining instrumented values of output that are uncorrelated with endogenous shocks to pollution. The key identifying assumption for our WTO instrument (Equation (10)) is that the pre-treatment trends are parallel for coastal and inner regions prior to China joining the WTO. Online Appendix 11 plots coefficients and 95% confidence intervals from regressing county-level output on year dummies interacted with $I_{c \in Coast}$ conditional

---

[26] We define "dirty" and "clean" based on the 3-digit SIC codes in Mani and Wheeler (1998).
[27] Environmental protection measures were first added to government officials' promotion criteria in December 2005. See http://www.gov.cn/zwgk/2005-12/13/content_125680.htm (in Chinese).

on county fixed effects. The interaction terms (normalized to zero in 2001) show no obvious trend prior to 2002 and display an upward trend after 2002.

Table 8 reports the estimates of Equations (9) and (10) using data for our sample period. The instrument is reasonably powerful and yields an elasticity of 1.43 for $PM_{2.5}$ with respect to output which is statistically very significant. The OLS estimate is about one-third of this consistent with attenuation bias due to endogeneity.

[Insert Table 8 here.]

6. General-equilibrium effects

6.1 The model

To simulate the dynamic, general-equilibrium effects of pollution on output we calibrate an IAM that integrates polluting activities into a standard growth model of a market economy (Xepapadeas (2005) provides an overview of such models). There is a broad literature using IAMs to model climate change but a few focus on particulate matter (e.g., Carbone and Smith, 2008; Aldeco *et al.*, 2019). Like these papers, we do not model how $PM_{2.5}$ is emitted and accumulates in the atmosphere because it hovers in the air for a much shorter time than measured by our annual data (Aldeco *et al.*, 2019). The model treats pollution as a productivity-reducing input and undesirable output of firm production. The model dynamics capture the effects of capital-stock accumulation which is important given China's rapid growth during our sample period.

The model is an intertemporal, general-equilibrium model in which a representative agent chooses period-by-period consumption to maximize utility discounted by the rate of social time preference and subject to an economic constraint and a pollution-damage function. It assumes decentralized utility-maximizing households and perfectly competitive profit-maximizing firms (a Ramsey model). The production and pollution-damage functions are those in the illustrative models that inform our partial-equilibrium estimation. Population and technology grow exogenously while capital accumulates according to the optimal rate of investment.[28]

The model maximizes the sum of lifetime discounted utility for a representative consumer in the population P_t using a logarithmic utility function of per-capita consumption ($c_t = C_t/P_t$) where C_t is aggregate consumption. We assume that the fraction of the population in the work force remains the same over time ($P_t = ML_t$):

$$\max_{c_t} \sum_{t=1}^{T} ML_t ln[c_t](1+\rho)^{-t}, \quad (11)$$

---

[28] Because we assume exogenous technological change, output will not grow in the long run without technological progress. However, our sample period is short and the capital stock does not accumulate rapidly enough that it is affected by the long-run growth rate in our simulations.

where ρ is the annual rate of social time preference. Output is given by Equation (6) which captures both pollution effects that we find in our partial-equilibrium analysis: changes in productivity and labor supply (effective units of labor). The pollution-damage function that relates contemporaneous pollution to output is given by Equation (5).

Gross output is divided between investment (I_t) and aggregate consumption:

$$Q_t = C_t + I_t, \text{ (12)}$$

and the law of motion for capital is:

$$K_t = (1 - \delta)K_{t-1} + I_t, \text{ (13)}$$

where δ is the rate of capital depreciation.

6.2 Simulation

We simulate the model to fit economy-wide data for China (Zeileis, 2019; Feenstra *et al.*, 2015) during our sample period using our partial-equilibrium estimates of θ, κ, and μ. We simulate over a sufficient number of periods that the outcome during our sample period is not significantly affected by endpoint conditions. We found that simulating 100 years (1996 to 2095) is sufficient. We assume that pollution's effect on output ($\theta + \kappa$) is constant over the entire 100 years (i.e., firms cannot engage in avoidance behavior) but we allow for exogenous improvements in abatement technology (μ decreases to 1.0 in 2095) that occur smoothly beginning after the sample period. Our chosen parameters result in simulated levels of output and pollution that are close to the actual during the sample period. Online Appendix 12 provides evidence of the fit and more details on data sources and how the model is calibrated and solved.

We set λ_t (the fraction of output produced by the manufacturing sector) equal to its actual values from 1996 to 2017 (*China Statistical Yearbook*, 2018) and we assume it remains constant at the 2017 value thereafter. While a more realistic model would allow for separate services and manufacturing sectors, manufacturing is a relatively constant fraction of GDP over the sample period (45.8% in 1998 versus 46.9% in 2007). The labor share $(1 - \gamma)$ is 0.425 based on the average labor share in China from 1996 to 2017 and the initial capital stock in 1995 is its actual value of USD 10.18 trillion. TFP is initialized to its actual value in 1996 and we assume it grows at 7.96% per annum from 1996 to 2017 based on Brandt *et al.* (2012) after which it declines to 3.0% in 2033 and then remains constant. The actual capital, labor share, and TFP data are from Zeileis (2019) and Feenstra *et al.* (2015). The depreciation rate is 0.09 based on Brandt *et al.* (2012) and the consumer's rate of time preference is 0.04 based on Chang *et al.* (2015). The pollution-damage function intercept (B) is set to fit average

PM$_{2.5}$ concentrations over the sample period.[29] Population is based on actual and projected data from the United Nations.[30]

After calibrating the model, we run counterfactuals to assess pollution's general-equilibrium effects. We vary μ_t slightly to generate a local derivative of output with respect to pollution. A 1% decrease in PM$_{2.5}$ over all years increases manufacturing output by 0.28% on average over the sample period compared to the partial equilibrium increase of 0.17%. A one percent exogenous reduction in PM$_{2.5}$ increases the average firm's value added by CNY 35.9 (USD 4.7) thousand annually and increases total value added across all firms by CNY 5.7 (USD 0.75) billion annually (0.039% of China's GDP). To assess the sensitivity of these results to the uncertainty in our partial-equilibrium estimates we re-simulated the model using the 95% confidence intervals for the effect of pollution on output $(\theta + \kappa) \in [-0.329, -0.014]$ and effect of output on pollution $\mu \in [0.713, 2.15]$. The elasticities ranged from -0.020 to -0.515.

Output is more responsive to pollution in the dynamic, general-equilibrium model because of the tradeoff between current and future consumption. Because future consumption is discounted, an exogenous pollution increase results in a smaller decrease in current than future consumption. This lowers current investment and thereby the accumulation of capital stock which lowers output more (in percentage terms) than is the case in a static model.[31] Because China's economy is growing during this time, the response to a pollution increase is lower in absolute value initially (-0.22 in 1998) than it is in later periods (-0.31 in 2007) when the capital stock has grown and the tradeoff between consumption and investment is not as stark.

These results can be used to directly evaluate the general-equilibrium effects of policies. For example, China's Air Pollution Prevention and Control Action Plan enacted in 2013 stipulated that by 2017 PM$_{2.5}$ concentrations should fall by 25%, 20%, and 15% in Beijing-Tianjin-Hebei, the Yangtze River Delta, and the Pearl River Delta regions respectively[32] which are China's main industrial centers. Using the midpoint of these three goals (20%) and scaling our elasticity estimate linearly, the productivity boost from reaching this target would be 5.6% (0.77% of GDP) if derived from exogenous decreases in pollution.

It is useful to place these benefits in context by quantifying the costs of reducing PM$_{2.5}$. Unfortunately, we are unaware of direct estimates of the costs of PM$_{2.5}$ reductions. The best we can do is to rely on indirect measures for other pollutants

---

[29] Xepapadeas (2005) discusses the issue of modeling concentrations rather than emissions in IAMs.
[30] Data are found at https://population.un.org/wpp/.
[31] In a static analysis with the constant-elasticity relationship between output and pollution in Equations (5) and (6), an exogenous increase in pollution will result in an output decrease equal to the partial-equilibrium estimate (-0.17). This will not be the case either with other functional forms in a static analysis or with dynamics.
[32] Issued by the State Council on September 10, 2013 (http://www.gov.cn/zwgk/2013-09/12/content_2486773.htm).

estimated from policy interventions. The most useful estimate comes from the US. Pollution-intensive industries in counties subject to regulation under the Clean Air Act lost on average USD 7.9 billion of output annually relative to counties that were not (Greenstone, 2002). At the same time, air pollution declined by roughly 12% more in non-attainment relative to attainment counties (Chay and Greenstone, 2005).[33] Combining these two estimates, a back-of-the-envelope calculation indicates that a 1% reduction in pollution costs USD 0.66 billion. This is a lower bound on the costs because the estimate from Greenstone (2002) is a partial equilibrium estimate that does not consider the effect of output on pollution. This is 83% of our estimate of the benefits of reducing $PM_{2.5}$ by one percent (USD 0.75 billion annually).

There are other studies that provide more indirect measures of the costs of reducing pollution. The pollution-reduction measures taken during the 2008 Beijing Olympic Games decreased PM_{10} concentrations from 24% to 33% in the city (Chen *et al.*, 2013; He *et al.*, 2016). Restricting 1% of vehicles in Beijing one-day-per week reduces PM_{10} by 1% (Viard and Fu, 2015). A one standard deviation increase in subway density in Beijing reduced particulate matter by 2% (Li *et al.*, 2019) and a subway opening decreases particulate concentrations by 4% around a city center (Gendron-Carrier *et al.*, 2018). Derivation of these costs and explanations of the pollutants are in Online Appendix 13.

Our simulation has several important simplifications that could be relaxed with further modeling or data collection or that are better suited to other settings. First, we assume that China is a closed economy. Trade could be incorporated in the model at the expense of much greater complexity (Xepapadeas, 2005 provides examples) and loss of transparency. Our abstraction from this is an obvious simplification given that China is a large importer-exporter during our sample period. We implicitly assume that the consumer is representative of both domestic and export consumers and input prices are determined domestically rather than worldwide.

Second, we do not treat pollution as a source of disutility. That is, air pollution is separable from consumption and leisure in utility. Awareness of air pollution was limited during our sample period[34] and unlikely to directly affect consumer purchases. It would be useful to analyze this using later data (Carbone and Smith (2008) provides a model; Ito and Zhang (2020) provide an estimate of the marginal willingness to pay for air quality). This would allow for two possible effects of pollution externalities absent from our model: pollution could affect consumption and labor supply which would in turn affect output and thus pollution. Besides these, pollution may affect health and mortality negatively which we ignore.

---

[33] This is for "total suspended particulate," an older measure of particulate pollution but the closest measure available at that time to the pollutant we examine.

[34] Ito and Zhang (2020: Appendix A.4) marks increased awareness beginning in 2013: from 2006 to 2012 annual media mentions of air pollution in China averaged 158 headlines but jumped to 1,327 (1,549) in 2013 (2014).

Third, we do not allow for endogenous changes in abatement technology over time. Abatement efforts are not significant during our sample period.[35] Allowing for endogenous abatement efforts would be important in analyzing later time periods and could be incorporated by allowing the pollution-output elasticity to depend on a stock of knowledge which accumulates through research and development expenditures (Buonanno *et al.*, 2003; Gillingham *et al.*, 2008). As Gillingham *et al.* (2008) argue, it is useful to endogenize technological change to allow policies to affect the direction of technological change toward abatement efforts over time.

Fourth, we assume manufacturing is an exogenous fraction of total output. In other contexts or time periods this may significantly depart from actual conditions in which case multiple sectors could be accommodated as in Carbone and Smith (2008). Multiple sectors could also allow for endogenous choice of "dirty" versus "clean" intermediate inputs which would be important in contexts with significant abatement efforts.

7. Conclusion

Using a large micro dataset on manufacturing firms in China, we estimate the effect of air pollution on productivity. To deal with the reverse causality of output and pollution and other potential endogeneity issues we take an instrumental variable approach. For the effect of pollution on output we use thermal inversions, which are meteorologically determined. The approach attenuates the endogeneity bias and indicates a significant negative effect of air pollution on productivity. For the effect of output on pollution we use the differential effects of China's entry into the WTO on coastal versus inner regions of China. Combining these in an integrated assessment model we quantify the general-equilibrium effects of pollution on output.

Our study shows a significant economic loss in productivity, and therefore output, in China due to air pollution. This also suggests a huge social benefit of improving air quality via increased productivity and output. Our study contributes to the emerging literature on air pollution's effect on short-run productivity by providing comprehensive, nationwide empirical evidence that captures all channels through which pollution can affect productivity and taking account of the general-equilibrium effects of output on pollution. These estimates can be used directly for short-run effects in cost-benefit analyses of broad-based environmental policies.

Our findings shed new light on the debate about whether environmental regulations positively or negatively affect firm competitiveness (Jaffe *et al.*, 1995; Greenstone *et al.*, 2012). Historically, this debate has focused on the extent to which decreased competitiveness from environmental compliance costs is offset by process innovations that are both cleaner and of lower cost. Our results confirm another

---

[35] As discussed in footnote 27, government officials were not evaluated on environmental criteria until December 2005 so incentives to invest in abatement efforts was limited prior to this time.

channel that influences this debate. Environmental regulations that decrease air pollution will in turn increase productivity and at least partially offset the decreased productivity due to complying.

Since our identification relies on yearly variation we are unable to estimate long-run effects of pollution on productivity. In the long run firms may take steps to respond to pollution such as protecting indoor workers or moving to lower-pollution areas to boost productivity. Workers also may move in the long run to avoid pollution, especially high-skilled workers who have a greater willingness to pay to avoid pollution. We find little evidence of such sorting in our short-run results but this may occur over longer periods and would attenuate the productivity effects.

Although we can capture all channels by which pollution can influence productivity, we are unable to decompose the exact channels by which pollution lowers productivity. Significant effects on productivity per hour would indicate that there are large benefits from protecting workers from air pollution while at work. Effects on hours worked might indicate exposure to pollution by a worker's family members in addition to workplace exposure.

Our general-equilibrium model of pollution effects could be expanded along several dimensions including allowing for investments in abatement technologies, influence of trade, consumer disutility from pollution, and multiple sectors. These extensions would allow an evaluation of other avenues that environmental policies may impact.

Figure 1: Time trend of air pollution and value added in China (1998 to 2007)
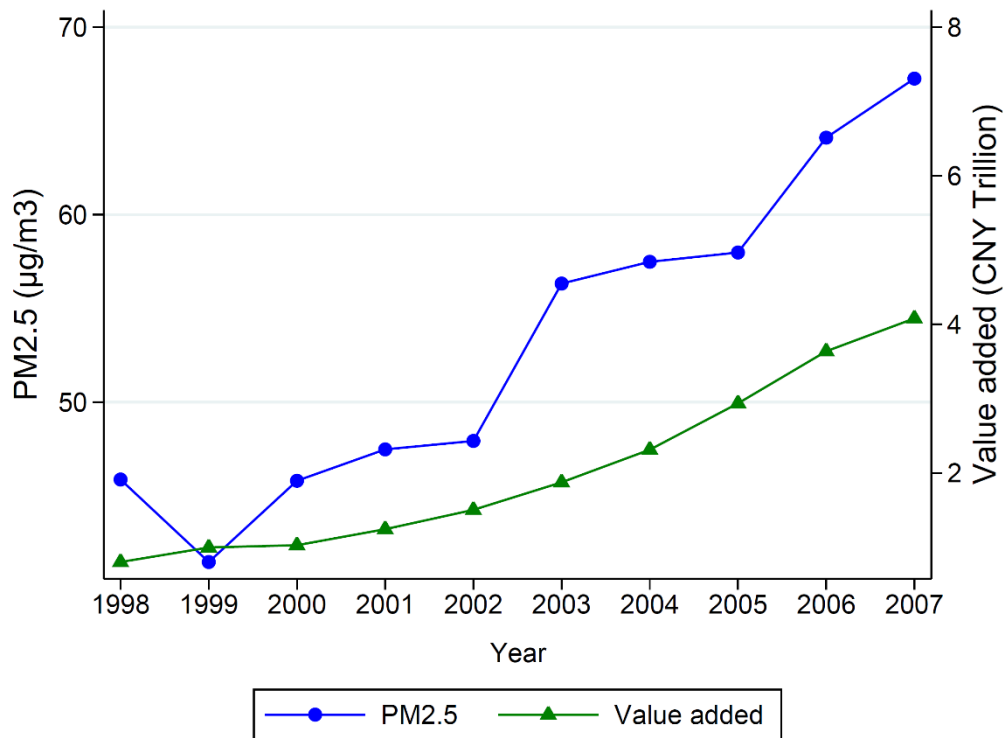

Notes: This graph displays national average of county-level PM$_{2.5}$ and aggregate value added of China's manufacturing sector from 1998 to 2007. Value added includes all state-owned enterprises (SOEs) and all non-SOEs with sales above CNY 5 million winsorized as described in the paper.

Table 1: Summary statistics for firm-level productivity and county-level pollution data

Variables	Mean	Standard deviation	Min	Max
Firm-year sample				
Firm				
Value added (1,000 CNY)	12,821	23,540	74	366,426
Employment (person)	207	299	10	3,013
Capital (1,000 CNY)	14,531	30,872	64	350,801
Output per worker (1,000 CNY/worker)	88	160	0.13	16,248
Total factor productivity (OP estimates)	2.91	1.03	-3.23	8.44
Total factor productivity (LP estimates)	5.38	0.97	0.01	10.03
County-year sample				
Air pollution				
Particular matter ($PM_{2.5}$) ($\mu g/m^3$)	53.52	25.46	2.62	134.84
Thermal inversions				
Annual days with thermal inversions	156.95	78.75	0.00	333.00

Notes: Firm-year sample size: 1,593,247 including 356,179 firms. County-year sample size: 25,359 including 2,755 counties. Sample period: 1998-2007. Total factor productivity are estimates based on Olley-Pakes (1996) (OP) and Levinsohn-Petrin (2003) (LP) instrumenting approaches.

All columns are county-year data and aggregate all firms to the county level. All models use annual number of days with thermal inversions as first-stage instruments. All models include year fixed effects, county fixed effects, and weather controls in both stages. Standard errors are clustered at the county level and reported in parentheses. *** $p<0.01$, ** $p<0.05$, * $p<0.1$. The KP F-statistic is the Kleibergen-Paap Wald rk F-statistic for weak identification in the first stage (Kleibergen and Paap, 2006).

Appendix 7: Sensitivity of entry and exit regressions to censoring of "below-scale" firms

This appendix describes how we modify the entry and exit rates to test the sensitivity of the entry and exit regressions to censoring on below-scale firms.

Using the 2004 census data, determine the number of below-scale firms in county c as a fraction of below-scale firms nationwide in 2004:

$$bsfrac_c = \frac{bs_c}{\sum_c bs_c}, \text{ (A1)}$$

where bs_c is the number of below-scale firms in county c in year 2004. The unadjusted entry rate for county c in year t is:

$$entry_{ct} = \frac{a_{ct}}{f_{ct}}, \text{ (A2)}$$

where a_{ct} is the number of firms that appeared in the sample in county c in moving from year $t-1$ to year t and f_{ct} is the number of firms in county c in year t.

We modify each county's entry rate to assume that r percent of firms that appeared nationwide ($\sum_c a_{ct}$) moved from being "below- scale" to being "above-scale" rather than entering. We apply this adjustment proportionally to each county based on its fraction of "below-scale" firms in 2004 bounding the rate to be non-negative:

$$\widehat{entry}_{ct} = max\left[0, entry_{ct} - bsfrac_c * \frac{r*\sum_c a_{ct}}{\sum_c f_{ct}}\right]. \text{ (A3)}$$

We modify the exit rate in an analogous manner to test the sensitivity of the exit regressions to truncation for "above-scale" firms. The unadjusted exit rate for county c in year t is:

$$exit_{ct} = \frac{d_{ct}}{f_{ct}}, \text{ (A4)}$$

where d_{ct} is the number of firms that disappeared from the sample in county c in moving from year t to year $t+1$.

We modify each county's exit rate to assume that r percent of firms that disappeared nationwide ($\sum_c d_{ct}$) became "below-scale" firms rather than exiting. As with the modified entry rate, we apply this adjustment proportionally to each county based on its fraction of the nation's "below-scale" firms in 2004 bounding the rate to be non-negative:

$$\widehat{exit}_{ct} = max\left[0, exit_{ct} - bsfrac_c * \frac{r*\sum_c d_{ct}}{\sum_c f_{ct}}\right]. \text{ (A5)}$$

We then re-estimate our exit regressions varying the value of r between 0 and 1.

Notes: All models include firm fixed effects, year fixed effects, and weather controls. Sample period: 1998-2007. "High-inversion regions" in Column (2) are defined as counties with annual number of days with an inversion above the median. Standard errors are clustered at the firm level and reported in parentheses. *** $p<0.01$, ** $p<0.05$, * $p<0.1$. The KP F-statistic is the Kleibergen-Paap Wald rk F-statistic for weak identification in the first stage (Kleibergen and Paap, 2006).

Appendix 11: Test of parallel trends for coastal versus inner regions before China joins the WTO in late 2001
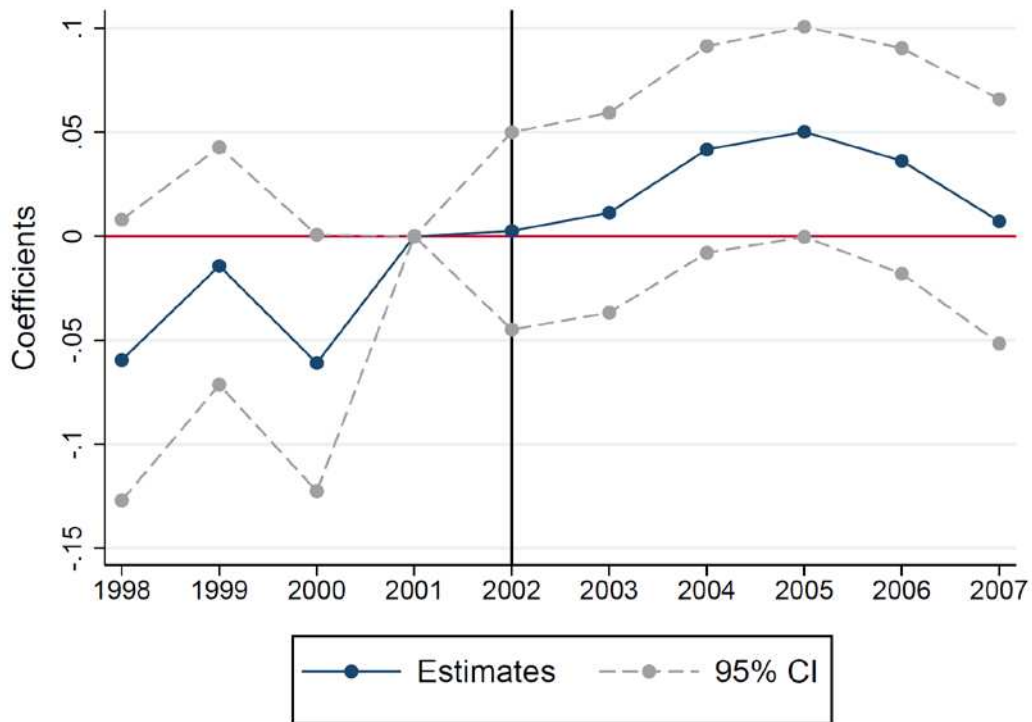

Notes: β_{1t} coefficients and 95% confidence intervals from estimating a regression of county-level output on county fixed effects, year fixed effects, and interactions between year fixed effects and coastal counties: $Q_{ct} = \beta_0 + \sum_t \beta_{1t}\rho_t I_{c\in Coast} + \alpha_c + \rho_t + \nu_{it}$ normalizing β_{12001} to zero.

Appendix 12: General-equilibrium model solution, calibration, and data

Model solution

Substituting Equation (5) into (6) (both from the paper) we obtain:

$$Q_t = \left[\tilde{A}_t K_t^{\gamma} L_t^{1-\gamma}\right]^{\eta_t}, \text{ (A1)}$$

where $\eta_t = 1/[1 - (\theta + \kappa)\mu_t]$ and $\tilde{A}(t) = \left[B^{\theta+\kappa}\lambda(t)^{(\theta+\kappa)\mu_t}A_t\right]$.

Substituting Equation (A1) into (12) from the paper and then solving for C_t:

$$C_t = \left[\tilde{A}_t K_t^{\gamma} L_t^{1-\gamma}\right]^{\eta_t} - I_t. \text{ (A2)}$$

Using Equation (13) from the paper for I_t and substituting it into (A2):

$$C_t = \left[\tilde{A}_t K_t^{\gamma} L_t^{1-\gamma}\right]^{\eta_t} - [K_t - (1-\delta)K_{t-1}]. \text{ (A3)}$$

Now substituting this for C_t in Equation (11) from the paper we can transform the optimization problem to a choice of capital stock period-by-period:

$$\genfrac{}{}{0pt}{}{max}{K_t \geq 0} \sum_{t=1}^{T} ML_t \ln\left[\frac{\Gamma(K_t)}{ML_t}\right](1+\rho)^{-t}, \text{ (A4)}$$

where $\Gamma[K_t] = \left[\tilde{A}_t K_t^{\gamma} L_t^{1-\gamma}\right]^{\eta_t} - [K_t - (1-\delta)K_{t-1}]$ subject to $[K_t - (1-\delta)K_{t-1}] \geq 0$ and $\Gamma[K_t] \geq 0$.

We use the Matlab function *fmincon* to solve Equation (A4) over 100 periods (1996 to 2095) choosing the optimal capital-stock path given the initial capital stock in 1995. We simulate 100 years to ensure that endpoint conditions do not unduly impact the outcome over the sample period. The parameter values described below allow us to match actual output and pollution reasonably well. Figures A1 and A2 below compare actual and simulated values of output and pollution over the sample period. Actual output is based on the variable "real GDP at constant 2011 national prices" from the Penn World Tables (Zeileis (2019) and Feenstra *et al.* (2015)). Average PM$_{2.5}$ concentrations are calculated from the data described in the text and are the same as those in Figure 1 in the paper.

To simulate the general-equilibrium effects of an exogenous change in pollution we slightly adjust the value of μ_t multiplicatively and equally across all periods and re-optimize the model to obtain an elasticity of output with respect to pollution. The estimate was similar for a range of variations in both directions (μ during the sample period ranging from 0.98 to 1.2).
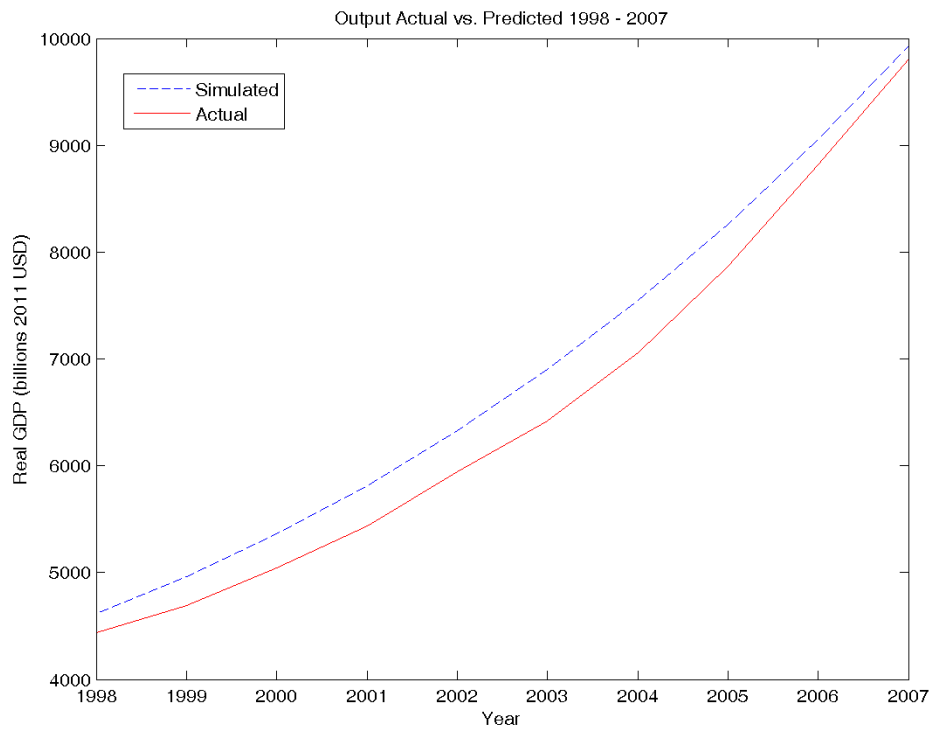

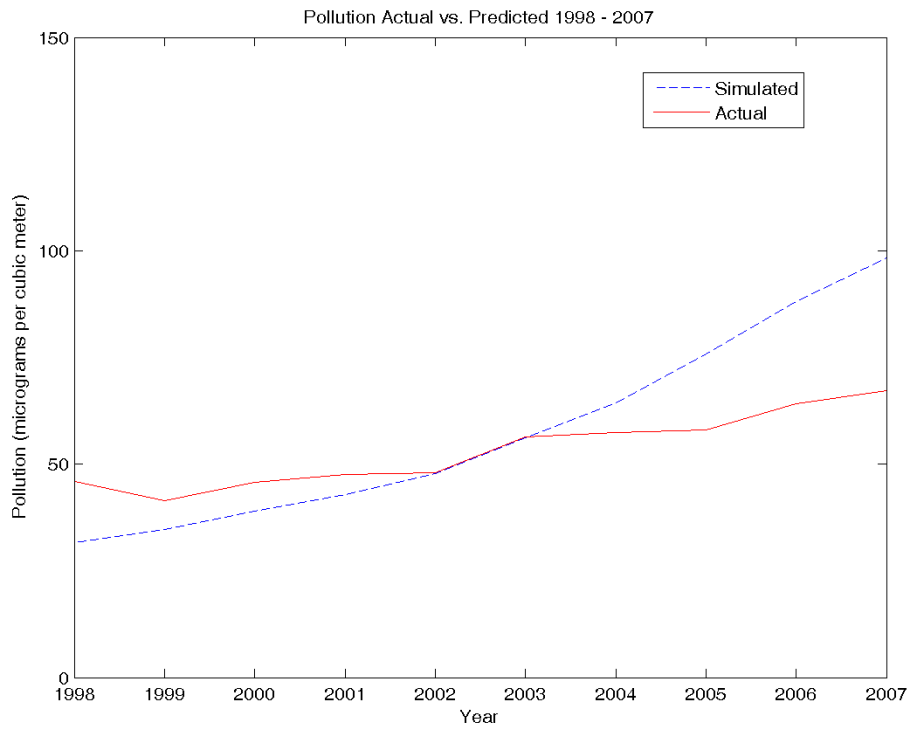

Figure A1: Simulated versus actual output

Output Actual vs. Predicted 1998 - 2007

Figure A2: Simulated versus actual pollution concentrations

Pollution Actual vs. Predicted 1998 - 2007

Parameter calibration

We calibrate the model to China's economy during our sample period using the following parameter values:

1) The consumer's rate of time preference (ρ) is set to 0.04 in all years – a value commonly used in macroeconomic simulations (*e.g.*, Chang *et al.*, 2015).
2) The labor share ($1 - \gamma$) is set to 0.425 in all years based on the average labor share in China from 1995 to 2017 based on the variable "share of labor compensation in GDP at current national prices" in the Penn World Tables (Zeileis, 2019 and Feenstra *et al.*, 2015).
3) The elasticity of output with respect to pollution ($\theta + \kappa$) is set to our partial-equilibrium estimate of -0.1710 in all years.
4) The depreciation rate (δ) is set to 0.09 in all years based on Brandt *et al.* (2012) from which our firm productivity data is taken.
5) The elasticity of pollution with respect to output (μ) is set to 1.4317 through the year 2007 based on our differences-in-differences estimates as described in the paper. After 2007 we assume that this value declines smoothly to 1.0 in the year 2095 (the last year of our simulation). This is to account for China's projected improvements in emissions control over time.
6) The share of total output comprised of manufacturing (λ) is set year-by-year based on the share of GDP in first, second, and tertiary industries (*China Statistical Yearbook*, 2018) from 1996 to 2017. After 2017 we assume that it remains constant at the value in 2017 (0.405).
7) The baseline level of PM$_{2.5}$ concentrations (B) is set to minimize the difference between the average actual and simulated values of concentrations across all years:
    $E\left[\Omega_t / (\lambda_t \hat{Q}_t)^{\mu_t}\right] = 0.0005486$ where $\hat{Q}_t$ are simulated values with $B = 1$.

Exogenous data

Population (P): actual and projected population by the United Nations from 1996 to 2095 (https://population.un.org/wpp/).

Augmented TFP $(\tilde{A})$: the 1996 value is based on the variable "residual TFP" in the Penn World Tables (Zeileis, 2019 and Feenstra *et al.*, 2015). From 1997 to 2017, we assume that it grows at 7.96% per annum based on estimates in Brandt *et al.* (2012) using manufacturing sector data from 1998 to 2007. Beginning in 2018 we assume that the growth rate declines to 3.0% in 2033 after which it remains at 3.0% for the remaining years.

Initial Capital Stock (K_{1995}): 1995 value of the variable "Capital stock at constant 2011 national prices" in the Penn World Tables (Zeileis, 2019 and Feenstra *et al.*, 2015).

Endogenous data (for calibration)

Output (Q): 1998 to 2007 data based on the variable "Real GDP at constant 2011 national prices" in the Penn World Tables (Zeileis, 2019 and Feenstra *et al.*, 2015).

Pollution (P): PM$_{2.5}$ concentrations in the sample period (Figure 1 in the main text).

Appendix 13: Derivations of estimates for pollution reduction costs

Chay and Greenstone (2005): The first stage of the paper's 2SLS estimation implies that total suspended particulates (TSPs)[1] declined by 12% more in non-attainment than in attainment counties in response to the US Clean Air Act. The estimates use data from 1970 and 1980.

Chen *et al.* (2013): Estimates that the Air Pollution Index (API) dropped 33% due to the regulations implemented during the 2008 Beijing Olympics.[2] The API is primarily attributable to PM_{10}[3] in 2008.

Fu and Gu (2017): Estimates the elasticity of the API with respect to toll rates across Chinese cities. Using data from 2011 to 2012 they find an elasticity of -0.15. The API is primarily attributable to PM_{10} during this time. To reduce the API by 1% the toll rate needs to increase on average from CNY 0.400 to 0.437.

Gendron-Carrier *et al.* (2017): Finds that particulate concentrations (measured by AOD) drop by 4% in a 10-kilometer radius around a city center following a subway system opening. The paper uses a sample of 171 cities across Asia, Europe, North America, South America, Australia, and Africa between August 2001 and July 2013.

Li *et al.* (2019): Estimates the effects on the API and Air Quality Index (AQI)[4] of all subway expansions in Beijing from 2008 to 2017. A one-standard deviation increase in subway density (by their measure) decreases the API/AQI by 2%. The API is primarily attributable to PM_{10} during this time period and the AQI to $PM_{2.5}$.

Greenstone (2002): From 1972 to 1987, non-attainment counties that were subject to regulation under the US Clean Air Act lost approximately $75 billion of output (in 1987 dollars) in pollution-intensive industries relative to attainment counties. This is a lower bound on the costs since it is a partial-equilibrium estimate ignoring output's effect on pollution. Adjusting this for inflation using the Consumer Price Index this is $118.8 billion in

---

[1] TSP was a cruder measure of suspended particulates before the PM_{10} and $PM_{2.5}$ measures were introduced and is the closest to the pollutant measure we examine during our sample period.

[2] These measures included plant closures and relocations, furnace replacements, introduction of new emission standards, and stringent traffic controls.

[3] This is particulate matter smaller than ten micrometers in diameter.

[4] China reported the API through 2013 after which it began reporting the more sophisticated AQI.

2002 dollars (roughly the midpoint of our sample). This is $7.9 billion annually on average over the fifteen years. The pollutants include carbon monoxide (CO), O3, sulfur dioxide (SO_2), and total suspended particulates (TSP).

He *et al.* (2016): The first-stage of the paper's 2SLS estimation estimates that the air quality regulations during the 2008 Beijing Olympic Games[5] reduce PM_{10} concentrations by 24 to 26%.

Viard and Fu (2015): Beijing's API, which is primarily due to PM_{10} during the sample period, falls 21% in response to restricting 20% of cars one-day-a-week in the short run. This suggests reducing pollution by 1% requires restricting 1% of vehicles one-day-per week.
