Abstract

The paper features an analysis of cryptocurrencies and the impact of the COVID-19 pandemic on their effectiveness as a portfolio diversification tool. It does so by exploring the correlations between the continuously compounded returns on Bitcoin, Ethereum and the S&P500 Index, using a variety of parametric and non-parametric techniques. These methods include linear standard metrics such as the application of ordinary least squares regression (OLS) and the Pearson, Spearman, and Kendall's tau measures of association. In addition, non-linear, non-parametric measures such as the Generalised Measure of Correlation (GMC), and non-parametric copula estimates are applied. The results across this range of measures are consistent. The metrics suggest that whilst the shock of the COVID-18 pandemic does not appear to have increased the correlations between the crypto currency series, it does appear to have increased the correlations between the returns on crypto currencies and those on the S&P500 Index. This suggests that investment in cryptocurrencies is not likely to offer key diversification strategies in times of crisis, on the basis of evidence provided by this crisis

Keywords: Bitcoin, Ethereum, Copula, kernel estimation, non-parametric, GMC

1. Introduction

This paper explores the usage of cryptocurrencies as an investment diversification tool in times of crisis. The issue addressed is whether or not the correlation between cryptocurrencies, and that between cryptocurrencies and financial markets in general, increases during times of crisis, as represented by the recent Covid-19 pandemic. If the correlation between crypto currencies and other financial markets, in this case the S&P500 index, increases in times of crisis, then crypto currencies are a less attractive diversification tool than might be first thought.

December 31, 2021

The paper features the application of both customary forms of analysis, that are based on the application of OLS and correlation analysis, plus non-linear non-parametric methods. The former is based on the customary assumptions about the existence of linear relationships and the related Gaussian assumptions about the nature of the return distributions. However, the descriptive statistics presented in Table 2, and the direct tests of the nature of the return distributions, strongly reject the null hypothesis of the distributions being Gaussian. The OLS analysis and the results of Ramsey RESET tests also suggest the existence of non-linear relationships between the return series considered. Therefore a variety of non-parametric measures are applied. These include the recently developed non-linear Generalised Measure of Correlation (GMC), Zhang et al. (2012), and copula analysis fitted by means of Kernel regression. Thus, the copulas fitted are not based on Gaussian assumptions. Another attraction of nonparametric models, is that they discard any rigid structure for the data, and this approach nonparametric methodology really lets the data 'speak for itself'.

It has been suggested that the 2009 global financial crisis was mainly due to an unwarranted usage of the parametric Gaussian copula model for asset pricing (Salmon, 2009). The attraction of the non-parametric approach is that nonparametric models, which discard any rigid structure for the data, really let the data 'speak for itself'. Hence their attractiveness and their application provides a major feature and novelty in the current paper.

A novel feature of the world's financial markets, post the Global Financial Crisis (GFC), has been the emergence of cryptocurrencies. These originated in 2008, with the announcement by Satoshi Nakamoto (a pseudonym), of Bitcoin: a peer to peer electronic cash system, Nakamoto (2008). This involves a peer to peer version of electronic cash that facilitates payments being made between two parties without the guarantees and verification services of a financial institution. The system relies on a cryptographic verification system based on time-stamped entries in the blockchain. Nakamoto (2008) suggests that a weakness of trust-based systems, as founded on financial institutions, is that the cost of mediation increases transaction costs, limiting the minimum practical transaction size and cutting off the possibility for small casual transactions, and suggests there is a broader cost in the loss of ability to make non-reversible payments for non-reversible services.

A system based on cryptographic proof avoids these drawbacks and can be used for small transactions. Every Bitcoin is made up of 100,000,000 satoshis (Bitcoin's smallest unit), which means that a bitcoin is divisible up to 8 decimal places. This allows people to purchase fractions of a bitcoin with as little as one U.S. dollar. Privacy is maintained in the Bitcoin system in a manner similar to that in a stock exchange. Thus, the time and size of individual trades, the "tape", is made public, with no disclosure of the transacting parties. A further feature of Bitcoin is that it is supply predetermined. This means that it has the potential to serve as a store of value and a proper medium of transaction that is insulated against inflation.

The coindesk website (<https://www.coindesk.com/price/bitcoin/>), as accessed on 19 September 2021, suggested that the market capitalization of the Bitcoin

market stood at 890.56 billion. This reflects a continued growth in the acceptance of Bitcoin. For example, from August 2020, Paypal customers in the US (except Hawaii) could buy, sell, hold, and pay at checkout with 4 different Cryptocurrencies on PayPal: Bitcoin, Ethereum, Litecoin, and Bitcoin Cash.

Bauer et al. (2018) suggest that Bitcoin is uncorrelated with standard asset classes in normal times and in times of crisis. They further suggest that Bitcoin tends to be used as a speculative investment and not as an alternative currency or medium of exchange. However, the measures of correlation used in their study are parametric, an issue that is a focus of investigation in this paper. Watorek et al. (2021) provide a large scale review of the development of the cryptocurrency markets applying tools from their native discipline physics. They use multifractal cross-correlation analysis, q -dependent detrended cross-correlation coefficients, non-linear correlations and multiscale characteristics, to analyse the characteristics of the cryptocurrency markets, via the use of high frequency data. They conclude that the cryptocurrency markets are gradually advancing to maturity but are still not fully developed markets like, for example, Forex. This is because there are still significant differences with regard to their liquidity and number of transactions.

Bouri et al. (2018) analyse the quantile conditional dependence between a global financial stress index and Bitcoin returns. The results from the copula-based dependence show evidence of right-tail dependence between the global financial stress index and Bitcoin returns. They suggest that overall, their results support the literature on the valuable role of Bitcoin returns (Bouri et al., 2017a, 2017b; Brière et al., 2015; Dyhrberg, 2016a, 2016b; Ji et al., 2017. Bouri et al. (2018) use parametric based copulas to capture dependencies, whereas a contribution of the current study is the use of non-parametric copula estimation techniques as a means for capturing dependencies.

Akhtaruzzaman et al. (2018), analyse the performance of portfolio diversification via the addition of Bitcoin to global industry portfolios and an investment grade bond index. They report lower dynamic correlations and substantial variation in relationships across industries and the bond index, and suggest the existence of lower dynamic correlations during times of downturn, on a sample that runs from 2011 to 2018. Briere et al. (2015) also report substantial diversification benefits from investment in Bitcoin. Gabri et al. (2021), apply various multivariate GARCH specifications, to model bitcoin and the joint dynamics of selected financial assets, and report low time-varying correlation of liquidity innovations over the period 2014–2019.

Gusmi et al. (2019), use a multivariate GARCH framework to assess spillover effects between bitcoin, gold and equities. They report that hedging strategies involving gold, oil, equities and Bitcoin serve to reduce portfolio risk. Quarni et al. (2021), examine spillover effects and portfolio diversification benefits from currency trading in both Bitcoin and foreign exchange markets. They report that Bitcoin provides significant portfolio diversification benefits for currency foreign exchange portfolios. Shazhad et al. (2020) also analyse the hedging characteristics of gold and Bitcoin for the G7 markets. They report that the out of sample hedging effectiveness of gold is superior to that of Bitcoin.

Conlon et al. (2020), explore the safe haven properties of Bitcoin, Ethereum and Tether from the perspective of international equity index investors. They report that Bitcoin and Ethereum are not a safe haven for the majority of international equity markets and that they add to downside portfolio risk.

However, Demir et al. (2020), use wavelet analysis to explore the hedging properties of Bitcoin (BTC), Ethereum (ETH), and Ripple (XRP) and COVID-19 cases/deaths, and suggest that there is evidence of hedging properties. Kristoufek (2020) uses quantile correlation to examine the correlations of Bitcoin and two benchmarks - the S&P 500 and VIX - and makes comparisons with gold. He suggests that the Bitcoin safe haven story is unsubstantiated and that gold is a preferable safe-haven.

Manavi et al. (2020) use a matrix correlation method to assess whether crypto currencies are a real commodity or/and a virtual currency. They compare 7 cryptocurrencies with a sample of the three types of monetary systems: 28 fiat money, 2 commodities, 2 commodity based indices, and 3 financial market indices. They report that other currencies are not correlated with crypto currencies.

Goodell and Goutte (2021) apply wavelet analysis to assess the impact of COVID-19 deaths on the levels of Bitcoin prices and report that they are positively related. Lahmiri and Bekiros (2020) apply entropy based metrics to assess the relative stability of crypto currencies as compared with a number of equity markets and report that cryptos showed more instability and more irregularity during the COVID-19 pandemic than international stock markets, which suggests they have relatively higher levels of risk. Grobys (2021) analyses the dynamic correlations between Bitcoin and US equity markets in the early stages of the pandemic, and he suggests that Bitcoin performed poorly in hedging US market tail risks. Drodz et al. (2020), apply fractal analysis to examine the topology of the crypto currencies markets and other fiat currency markets, in the early stages of the pandemic, and suggest that the topology during the pandemic differs, in some details, from other previous volatile periods.

Massoumi and Wu (2021) explore any similarity and dependence based on the full distributions of cryptocurrency assets, stock indices and industry groups. They characterize full distributions with entropies to account for higher moments and non-Gaussianity of returns. They measure divergence and distance between distributions using entropy based metrics. They report that the NASDAQ daily return has the most similar density and co-dependence with the Bitcoin daily return, and that the COVID-19 pandemic has increased co-dependencies.

It is obvious, from this brief review of the existing literature, that a large variety of different research methods have been applied to the examination of the riskiness and hedging properties of crypto currencies, producing varying and contradictory results. The current study adds to the literature by reporting the results of a variety of parametric and non-parametric measures of association, which incorporate both linear and non-linear measures of association. The aim is to explore whether these various methods produce similar results, or alternatively, whether the choice of metric is crucial to the nature of the results.

This study has parallels with that of Massoumi and Wu, in that it includes measures of co-dependencies that are non-linear and non-parametric. These

metrics differ in that they include the Generalised Measure of Correlation (GMC) (See: Zheng et al. (2012) and Vinod (2015)), and non-parametric copula-based metrics.

The paper is divided into four sections, a description of research methods follows in section 2, the results are presented in section 3, and a conclusion in section 4.

2. Research Methods

2.1. Basic measures

Chatterjee (2020) notes that the three classical measures of statistical association are Pearson's correlation coefficient, Spearman's ρ , and Kendall's τ . These coefficients are suitable for detecting linear or monotone associations, and they have well-developed asymptotic theories for calculating P-values. Yet these measures are not effective for detecting associations that are not monotonic, even in the complete absence of noise.

Given that prices series are likely to be non-stationary, I commence by estimating bivariate regressions of one price series logarithmic returns regressed on the logarithmic returns of another series. This provides an estimate of the Pearson correlation coefficient.

Logarithmic returns (r_t) are given by:

$$r_t = [\ln(p_t) - \ln(p_{t-1})]. \quad (1)$$

The Pearson Correlation coefficient (ρ) is the slope coefficient of the bivariate regression of the returns of one series on those of another. Given a pair of random variables, (X, Y) :

$$\rho_{X,Y} = \frac{Cov(X,Y)}{\sigma_X \sigma_Y}. \quad (2)$$

Spearman's rank correlation coefficient or Spearman's r_s , is a nonparametric measure of rank correlation or statistical dependence between the rankings of two variables. The Spearman correlation coefficient is defined as the Pearson correlation coefficient between the rank variables pertaining to the pair of variables.

For a sample of size n , the n raw scores X_i, Y_i are converted to ranks $R(X_i), R(Y_i)$ and r_s is computed as:

$$r_s = \rho_{R(X),R(Y)} = \frac{cov(R(X),R(Y))}{\sigma_{R(X)}\sigma_{R(Y)}}, \quad (3)$$

where ρ denotes the usual Pearson correlation coefficient, but applied to the rank variables.

Kendall's tau τ can be defined in terms of a pair (X, Y) , of joint random variables, $(x_i, y_j), \dots, (x_n, y_n)$, such that all the values of (x_i) and (y_j) are unique, (if we ignore ties for simplicity). then any pair of observations (x_i, y_j) , where $i < j$, are said to, be concordant, if the sort order of (x_i, x_j) and (y_i, y_j)

agrees, that is if $x_i > x_j$ and $y_i > y_j$, or vice versa. However, if $x_i > x_j$, but $y_i < y_j$, or vice-versa, they are said to be discordant.

The Kendall τ coefficient, is defined as:

$$\tau = \frac{(\text{number of concordant pairs}) - (\text{number of discordant pairs})}{\binom{n}{2}}, \quad (4)$$

where $\binom{n}{2} = \frac{n(n-1)}{2}$ is the binomial coefficient for the number of ways to choose two items from n items.

2.2. Copula models

Dependence modeling with copulas has attracted a lot of interest recently and copulas are established tools in many fields of applied statistics. Sklar (1959) states that any multivariate distribution function can be decomposed into the marginal distributions and a copula, which captures the dependence between variables. Sklar (1959) provides the basic theorem describing the role of copulas for describing dependence in statistics providing the link between multivariate distribution functions and their univariate margins. The argument proceeds as follows: let F be a d -dimensional distribution function with margins F_1, \dots, F_d . Then there exists a copula C such that for all $x = (x_1, \dots, x_d)' \in (\mathbb{R} \cup \{\infty, -\infty\})^d$,

$$F(x) = C(F_1(x_1), \dots, F_d(x_d)). \quad (5)$$

C is unique if F_1, \dots, F_d are continuous. Conversely, if C is a copula and F_1, \dots, F_d are distribution functions, then the Function F defined by (1) is a joint distribution with margins F_1, \dots, F_d . In particular C can be interpreted as the distribution function of a d -dimensional random variable on $[0, 1]^d$.

Though the copula of continuous random variables, can be generally defined, $X = (X_1, \dots, X_d) \sim F$ the problem in practical applications is the identification of the appropriate copula.

Standard multivariate copulas such as the multivariate Gaussian or Student-t as well as exchangeable Archimedean copulas lack the flexibility of accurately modeling the dependence among larger numbers of variables. Generalizations of these offer some improvement, but typically become rather intricate in their structure and hence exhibit other limitations such as parameter restrictions.

The approach taken in the current paper is to let the data speak for itself and estimate a copula that fits the characteristics of the data set. One of the major benefits of copula-based modeling is that inference for marginal distributions can be separated from the modeling of the dependence structure, i.e., the copula. In the estimation of the copula density C , it is most common to take a two-step approach: First, obtain estimates $F\hat{X}, F\hat{Y}$ of the marginal distributions. One convenient way of doing this is to use the empirical distribution function

as an estimator. The next step involves the defining of *pseudo observations* $(\hat{U}, \hat{V}) = (\hat{F}_X(X), \hat{F}_Y(Y))$. The copula density can then be estimated as the joint density of (\hat{U}, \hat{V}) . A common approach is to assume a parametric model for the copula density C and estimate using maximum likelihood. Yet the large variety of parametric copula models, frequently lack flexibility and bear the risk of misspecification. Nonparametric density estimators avoid some of these issues.

In the analysis that follows I make use of the R library package 'kdecopula', Nagler (2018). The package provides methods for estimation, bandwidth selection, simulation, and visualization of the copulas fitted.

2.3. Generalised Measure of Correlation (GMC)

Zheng et al., (2012) developed the concept of Generalized Measures of Correlation (GMC). They start with a linear regression model, and the partitioning of the variance into explained and unexplained components.

$$\text{Var}(X) = \text{Var}(E(X | Y) + E(\text{Var}(X | Y))), \quad (6)$$

whenever $E(Y^2) < \infty$ and $E(X^2) < \infty$. Note that $E(\text{Var}(X | Y))$ is the expected conditional variance of X given Y , so that $E(\text{Var}(X | Y))/\text{Var}(X)$ can be interpreted as the explained variance of X by Y . Thus, we can write:

$$\frac{\text{Var}(E(X | Y))}{\text{Var}(X)} = 1 - \frac{E(\text{Var}(X | Y))}{\text{Var}(X)} = 1 - \frac{E(\{X - E(X | Y)\}^2)}{\text{Var}(X)}.$$

The explained variance of Y given X can be defined similarly. Zheng et al. (2012) define a pair of generalised measures of correlation (GMC) as:

$$\{GMC(Y | X), GMC(X | Y)\} = \left\{ 1 - \frac{E(\{Y - E(Y | X)\}^2)}{\text{Var}(Y)}, 1 - \frac{E(\{X - E(X | Y)\}^2)}{\text{Var}(X)} \right\}. \quad (7)$$

This pair of GMC measures has some attractive properties. It should be noted that the two measures are identical when (X, Y) is a bivariate normal random vector. However, GMCs are nonzero while Pearson's correlation coefficient may have a zero value when two random variables are nonlinearly dependent. GMC has various connections to Pearson's correlation coefficient and the coefficient of determination in regression models, and they are identical to the squared Pearson's correlation coefficient when two random variables are related in a linear equation. A special case is where two random variables follow a bivariate normal distribution.

Vinod (2015) applied the GMC metric in an economic paper which featured an analysis of development economics markets in a study of 198 countries, and also developed the R library package 'generalCorr' (2020). Allen and Hooper (2018) used the metric to analyse causal relations between the VIX, S&P500, and the realised volatility (RV) of the S&P500 sampled at 5-minute

intervals. Allen and McAleer (2020) explore the antecedents of the GMC metric, in particular the work of the Scottish statistician Yule (1897).

The R library package by Vinod (2016), provided software tools for computing generalized correlation coefficients and the preliminary determination of causal directions among a set of variables. Newer versions provide further enhancements, and Vinod (2020), provides a generalization of the Granger-causality test statistic as the difference between two R^2 values of two flipped kernel regressions, to allow for nonlinear and nonparametric causal dependence between two time series. This metric is utilised to check causal paths between cryptocurrency return pairs and crypto currencies paired with S&P500 Index returns, in the two periods used in this study.

3. Results

4. Characteristics of the Base Series

The daily cryptocurrency data sets for Bitcoin and Ethereum were taken from Yahoo finance. The data set began on 7 August 2015 and ended on 23 July 2021, producing 2170 daily observations for the crypto currencies. An overall sample of 5 years of daily data was chosen because this afforded a sufficient number of data points within the sub-samples, for accurate analysis, whilst not averaging the results over an excessively long period, particularly in the first sub-sample. The S&P500 index series was drawn from the Federal Reserve Bank of St. Louis (FRED) database and covered the same period. However, there are fewer trading days for the US Stock Exchange, which is more impacted by public holidays than are cryptocurrencies. The three series were spliced together, missing observations were removed, and the total data set for the combined series consisted of 1504 daily observations. The data was then split into two sub periods, Pre-COVID-19, which ran from 7 August 2015 to 31 December 2019, consisting of 1107 daily observations. The post-COVID-19 data set, commenced on 2 January 2020 and terminated on 23 July 2021, consisting of 388 daily observations.

Graphs of the base price series and returns for the two sample time periods are shown in Figures 1 and 2. The three base series all show evidence of trending behaviour in both periods. Plots of the price levels and returns on the series in the post-COVID-19 period are shown in Figure 2. Kwiatkowski et al. (1992) unit root tests, or more commonly termed KPSS tests, were undertaken on the levels of the series, for both the pre and post- COVID-19 samples, with the tests including a trend. The results are shown in Table 1. These show that all three series: Bitcoin, Ethereum and the S&P500 index in levels, reject the null of stationarity at the 1 percent level. As a result, all the analyses were performed on the continuously compounded return series.

Descriptive statistics for these series are presented in Table 2. It is apparent in Table 2 that the two cryptocurrencies have higher mean returns, a greater range of returns, and considerably higher standard deviations, in both periods, than

those of the S&P500 return series. All series display negative skewness and high kurtosis, relative to a normal distribution, which would have a kurtosis of 3.

The results of four different tests of conformance to a normal distribution are reported in the bottom panels, below the descriptive statistics, in Table 2. All four tests: namely the Doornik-Hansen, Shapiro-Wilk, Lilliefors and Jarque-Bera tests, reject the null hypothesis of a Gaussian distribution, at greater than the one percent level, for all three return series, in both periods.

The Pearson correlation test is based on the assumption of linearity and conformance to a normal distribution. For this reason, the tests of association, reported in the paper, include non-parametric tests and non linear measures of association.

4.1. Simple Tests of Correlation

The most straightforward test of the degree of correlation between the base return series is to estimate the Pearson correlation coefficient by running linear regressions. The results of these regression for the pre-COVID-19 period are shown in Table 3.

The regression in Table 3 reveal a significant correlation between BITRET and ETRET in the pre-COVID-19 period with a coefficient of 0.21 which is significant at the 1 percent level and an Adjusted R-squared of 16.7. The Ramsey RESET test suggests that a linear relationship is not adequate. The addition of a squared ETRET term increases the Adjusted R-square to 17.8 per cent and both the ETRET term and the squared ETRET term are significant at a 1 percent level.

The results of a regression of the returns on Bitcoin and Ethereum regressed on the S&P500 Index return during period 1, are shown in Table 4. It is notable that neither of these regressions have a significant slope coefficient on the S&P500 Index return. The F values of these regressions are not significant.

These results suggest that there are potential diversification benefits from investing in cryptocurrencies in Period 1, the pre-COVID-19 period, given that they are not significantly related to the return on the S&P500 Index return series, on the basis of this metric.

These results are confirmed in Table 5 which reports the results of tests of the association between these three pairs of series in Period 1 using Kendall's tau. The two cryptocurrencies are significantly related on these metrics, but neither are related to the return on the S&P500 Index returns, in this pre-COVID-19 period.

4.2. Regression analysis in Period 2

Table 6 shows the results of pairwise regressions of the returns on the three series in the post-COVID-19 period. Ramsey Reset Tests were performed on each regression specification and the results, (not reported) suggested a non-linear relationship, so squared values of the independent variable were added to the regressions in all three cases. There was little change in the results across the two periods in the regression of BITRET and ETRET, The slopes coefficients were roughly 0.2 and Adjusted R-squares were around 20 percent in both periods.

The notable change was in the relationship between the cryptocurrencies returns and the S&P500 Index returns. In the pre-COVID-19 period the slope coefficients on SPRET were insignificant. In the second period, they become strongly positive and highly significant, though it must be borne in mind that the regressions include a significant coefficient on the squared term aswell. This reflects a marked change in the relationship.

4.3. Non-linear Non-Parametric Measures of Association in Period 1

The R library package `kdecopula`, Nagler (2018) was used to fit copulas to paired return series using kernel density estimates. The package contains functions which are used to estimate the copula density from data. The only mandatory input is an $n \times 2$ matrix of copula data, in effect data with standard uniform margins.

Bouri et al. (2018) suggest three advantages for the use of copulas in assessing dependence. First, the copula method is designed to capture the complex and non-linear dependence structure of a multivariate distribution, enabling scrutiny of both tail dependence and the asymmetric dependence. Second, the marginal behaviour and the dependence structure are separated by the framework of copulas. This facilitates model specification and model estimation. Copulas can jointly combine different univariate models through their copula functions. Finally, copulas are invariant to increasing and continuous transformations, see Ning (2010).

The empirical application of copulas to financial time series of returns and the method for fitting marginal distributions, was pioneered by Patton (2002), in his Ph.D thesis: "Applications of Copula Theory in Financial Econometrics", and a further description is provided in Patton (2006, pp: 536-537). He suggests the following models for the marginal distributions of a pair of return series:

$$X_t = \mu_x + \phi_{1x}X_{t-1} + \varepsilon_t \quad (8)$$

$$\sigma_{x,t}^2 = \omega_x + \beta_x \sigma_{x,t-1}^2 + \alpha_x \varepsilon_{t-1}^2 \quad (9)$$

$$\sqrt{\frac{\nu_x}{\sigma_{x,t}^2(\nu_x - 2)}} \cdot \varepsilon_t \sim iidt_{\nu_x}.$$

A GARCH(1,1) model with a t-distribution was used to estimate the marginal distribution for the return series. This provided a first approximation, given that the package includes code to transform the data to uniform marginals. (In the case of BITCOIN returns in period 1, an ARCH model was used, as GARCH failed to converge).

Table 8 provides a description of the results from fitting copulas to the paired series during the pre-COVID-19 period. The results are consistent with the previous estimates. There is a significant association between the returns on Bitcoin and Ethereum but a minimal association between the cryptocurrency returns and those on the S&P500 index. The diagrams in Panels A and C of Figure 3 show that the copula surfaces are fairly flat when crypto currencies are paired with S&P500 returns, and the contour density plots, particularly in panel C, are almost circular, depicting low levels of association. The first contour plot in each series in the Figures, shows the situation with uniform marginals.

A variety of measures of association are used in Table 8 and I shall comment briefly on the properties of some of the less frequently used ones. The Blomquist (1950) measure of association was developed for circumstances in which it would be valid under weak assumptions about the distribution of the data and easy to apply in practice. Blomquist (1950, p.593), suggests we consider two sample medians \tilde{x} and \tilde{y} . The cdf $F(x, y)$ is assumed to have continuous marginal cdf's $F_1(x)$ and $F_2(y)$ in order that the probability of obtaining two equal x - values or two equal y -values in the sample will be zero. Blomquist (1950, p.593), then

divides the x, y -plane into four regions by the lines $x = \tilde{x}$ and $y = \tilde{y}$. He then suggests that some information about the correlation between x and y can be obtained by the number of sample points, say n_1 , belonging to the first or third quadrants, compared with the number, say n_2 , belonging to the second or fourth quadrants. After suggesting a couple of further adjustments related to the total sample size, he then suggests that a measure of correlation can be defined as:

$$q' = \frac{n_1 - n_2}{n_1 + n_2} = \frac{2n_1}{n_1 + n_2} - 1 \quad (-1 \leq q' \leq 1). \quad (10)$$

Genest and Verret (2005, p. 521) note that: “testing for independence between two continuous random variables X and Y is an old but important problem that has been the object of much attention in the past century. Though a great deal of literature is available on the subject, test procedures based on Pearson’s correlation continue to be the most commonly used in practice. This is in spite of the well-known fact that this coefficient is merely a measure of linear association whose effectiveness, therefore, is questionable outside the normal paradigm, including for testing purposes”. They also suggest that all modern concepts of dependence and stochastic orderings are based on copulas, including Spearman’s rho, Kendall’s tau and other nonparametric alternatives to Pearson’s correlation coefficient.

Embrechts et al. (2002), point out that the dependence structure in a pair of variables (X, Y) with continuous distribution H and margins F and G is best characterised by C , its unique underlying copula, implicitly defined on the unit square by:

$$H(x, y) = C\{F(x), G(y)\}, \quad x, y, \in \mathbb{R}.$$

Modern concepts of dependence and stochastic orderings are based on copulas, which includes Spearman’s rho, Kendall’s tau and various nonparametric alternatives to Pearson’s correlation coefficient.

The copula of a random pair (X, Y) is unaffected by monotone increasing transformations of the margins. Given a random sample from $H (X_1, Y_1), \dots, (X_n, Y_n)$, the associated pairs of ranks $(R_1, S_1), \dots, (R_n, S_n)$ are maximally invariant and can be used for a test of the hypothesis $H_0 : H = FG$, or equivalently, $H_0 : C = \Pi$, with $\Pi(\mu, \nu)$ for all $\mu, \nu \in (0, 1)$. A test based on Kendall’s tau statistic can be written as:

$$\tau_n = \frac{2}{n^2 - n} \sum_{1 \leq i < j \leq n} \text{sign}(R_i - R_j) \text{sign}(S_i - S_j),$$

and can be used to reject the null hypothesis, for a large enough sample size n , where $3\sqrt{n} | \tau_n | / 2 > \Phi^{-1}(0.975) = 1.96$, where Φ stands for the cumulative distribution function of a standard normal variable.

Another option, based on Spearman’s rho:

$$\rho_n = -3 \frac{n+1}{n-1} + \frac{12}{n^3 - n} \sum_{i=1}^n R_i S_i,$$

leads to rejection of the null when the asymptotic P -value $2\Phi(-\sqrt{n} | \rho_n |)$ of the two-sided test is too small.

Several other independence test statistics of the form:

$$T_n^J = \frac{1}{n} \sum_{i=1}^n J\left(\frac{R_i}{n+1}, \frac{S_i}{n+1}\right)$$

with specific score functions j , often perform as well or better than standard parametric tests based on Pearson's empirical correlation r_n , for various classes of alternatives.

Bhuchongkul (1964) demonstrated that the van der Waerden statistic, W_n based on $J(\mu, \nu) = \Phi^{-1}(\mu)\Phi^{-1}(\nu)$ dominates r_n for alternatives of the form:

$$X_i = X_i^* + \Delta Z_i, \quad Y_i = Y_i^* + \Delta Z_i,$$

where X_i^*, Y_i^* and Z_i are mutually independent random variables and Δ is a scalar.

Genest et al (2010) discuss the close relationship between Spearman's (1906) footrule, which is a nonparametric measure of association, and Gini's (1914) coefficient. The Spearman footrule can be written as:

$$\varphi_n = 1 - \frac{3}{n^2 - 1} \sum_{i=1}^n |R_i - S_i|$$

whereas the indice de cograduazione semplice, introduced by Gini (1914), can be written as:

$$\gamma_n = \frac{1}{[n^2/2]} \sum_{i=1}^n \{|(n+1 - R_i) - S_i| - |R_i - S_i|\}.$$

The last two measures, reported in Tables 8 and 9, are based on information criteria. Let X and Y be a pair of random variables. If their joint distribution is $P_{(X,Y)}$ and the marginal distributions are P_X and P_Y the mutual information is described as:

$$I(X, Y) = D_{KL}(P_{(X,Y)} \| P_X \otimes P_Y)$$

where D_{KL} is the Kullback-Leibler divergence. Information theory was developed by Shannon (1948), and Fano (1949) developed the concept of mutual information.

Hamdan and Tsokos (1971) discuss Linfoot's (1957) informational measure of association between two random variables X and Y . The measure r_1 is based on the information gain r_0 in knowing that X and Y are mutually dependent with a given bivariate density function as compared with the original knowledge that X and Y are statistically independent. Linfoot (1957) suggested that if X and Y have a bivariate normal distribution with correlation coefficient ρ , then $r_0 = (-1/2)\ln(1 - \rho^2)$, which led to Linfoot's (1957) suggestion that an informational measure ρ_1 of ρ defined as:

$$r_1 = [1 - \exp(-2\rho_0)]^{1/2}$$

In the case of discrete random variables X and Y with bivariate probabilities p_{ij} ($i = 1, 2, \dots, s; j = 1, 2, \dots, t$) and marginal probabilities $p_i = \sum_j p_{ij}$ and $p_j = \sum_i p_{ij}$, r_0 takes the form:

$$r_0 = \sum_i \sum_j p_{ij} \ln \left[\frac{p_{ij}}{p_i \cdot p_j} \right].$$

It is also the case that r_0 is equivalent to Kullback's (1959) distance-like measure, between the correlated bivariate distribution, and the distribution under independence.

The various measures of association for the three combinations of the paired series returns, as reported in the lower panels of each section of Table 6, all tell a consistent story. The level of association between returns on Bitcoin and Ethereum, is above 0.5, on the basis of the Spearman, Van de-Waerden and Linfoot metrics. For the definition of these measures used, see, Nelsen (2006), Genest and Verret (2005), and Joe (1989).

Figure 3 Panel A: BITRET and SPRET

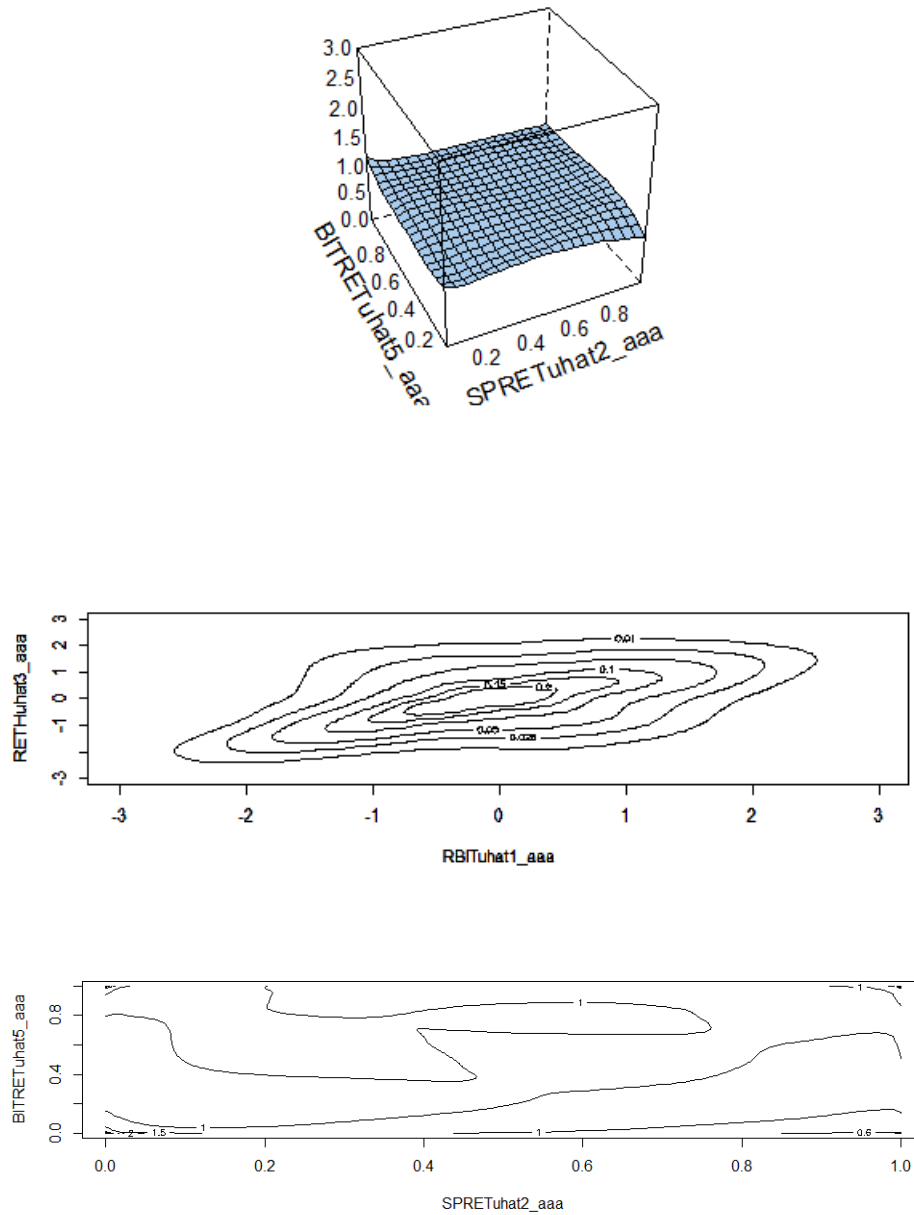

Figure 3 Panel B: ETRET and SPRET

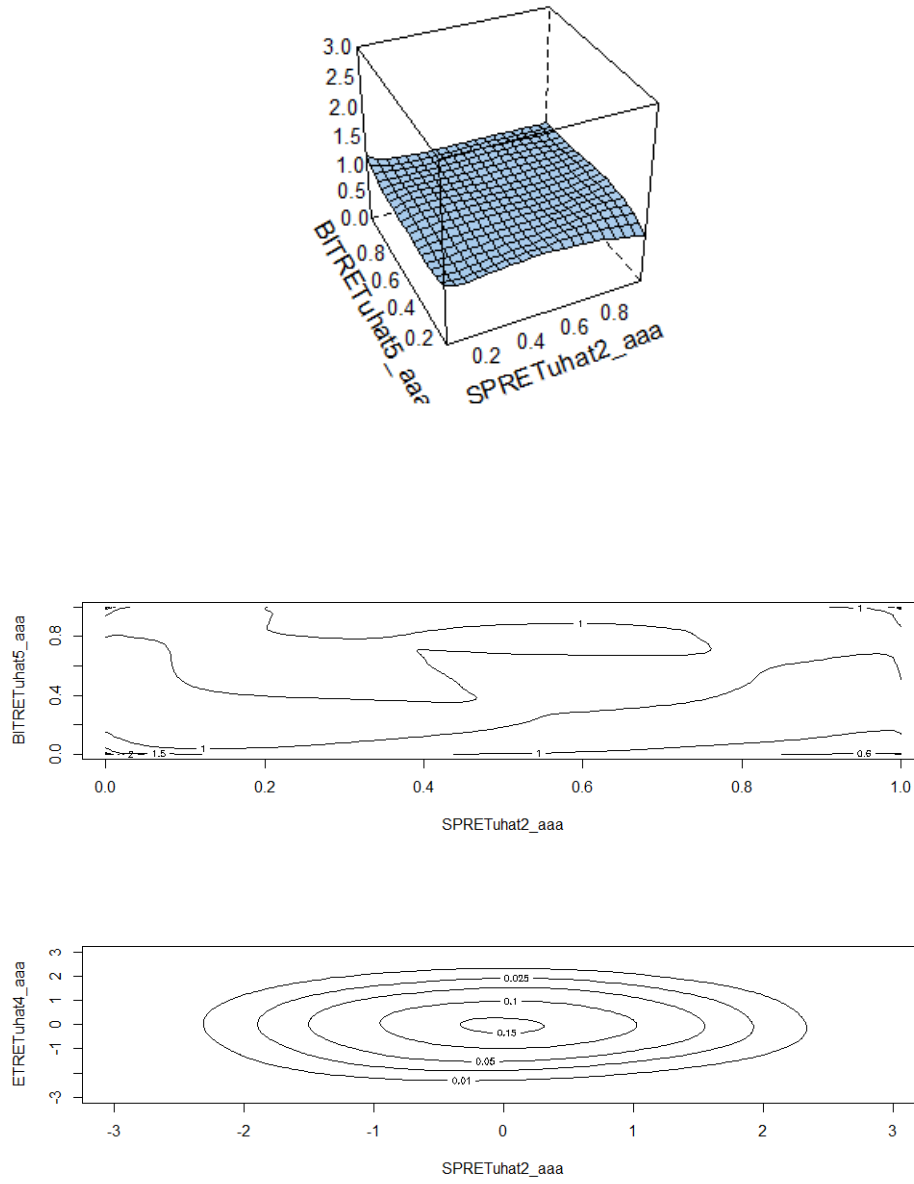

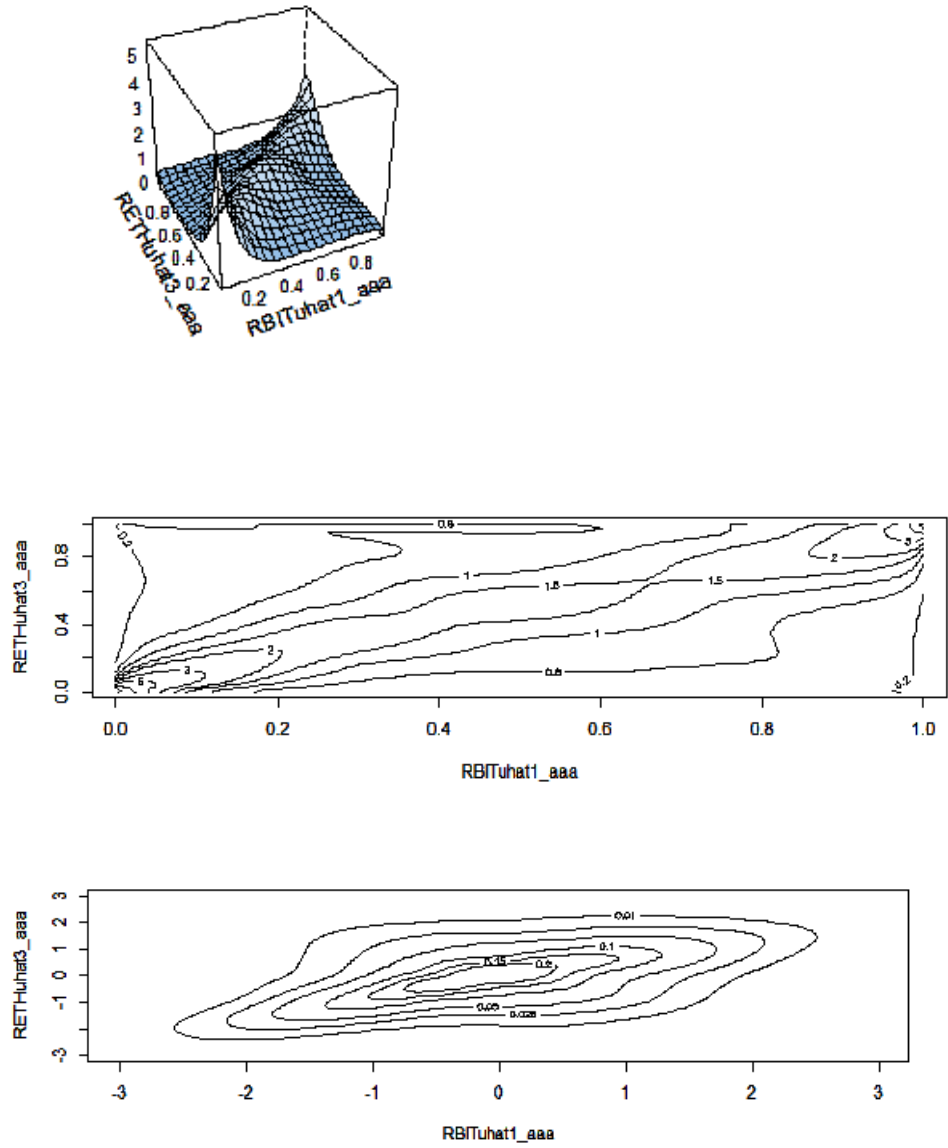

Figure 3 Panel C: BITRET and ETRET

Genest and Verret (2005), in their assessment based on simulations, suggested that whilst some dependence structures are easier to detect than others, the performance of rank tests can vary substantially from one set of alternatives to another. Pearson’s test seemed to be an acceptable procedure to use when the marginal distributions are normal, but not necessarily when they are not. Van der Waerden’s test is likely to perform well whenever Pearson’s test does, plus it has the additional advantage of being marginal-free. In terms of the limits of their simulation study, van der Waerden’s test seemed to hold a slight edge over Spearman’s and Kendall’s tests, which can be viewed as being essentially equivalent.

The results in Table 6 suggest that the degree of association between the two cryptocurrencies and the returns on the S&P500 index are virtually zero, as all the measures bracket zero, either positively or negatively. This suggests that in this period investing in cryptocurrencies does provide a potential diversification strategy. The concern is whether this remains the case when the market is subjected to the global shock of the pandemic? This is explored in the next sub-section.

4.4. Non-linear Non-Parametric Measures of Association in Period 2

Table 9 reports the results of non-parametric copula density estimation in Period 2. The correlations between the returns on the two cryptocurrencies and those on the S&P500 Index appear to increase markedly since the beginning of the COVID-19 pandemic. The estimates in Table 9 show that measures of association for BITRET and SPRET have increased in the case of the Kendall measure up to 0.15 whereas in the pre-COVID-19 period it was -0.01, and similarly the Spearman and Blomquist measures have increased from -0.01 in both cases up to 0.23 and 0.15 respectively. In short, all the metrics display a marked increase. The copula diagrams in Figure 4 confirm these changes.

Similarly, the estimates for ETRET and SPRET also show a marked increase. The Kendall and the Spearman measures stand at 0.08 and 0.11, whilst previously they were 0.01 and 0.02 respectively. However, the correlations between the two cryptocurrencies appear to have diminished. In the pre-COVID-19 period the Kendall and Spearman measures were 0.35 and 0.49 respectively, however, in the second period their values have fallen to 0.13 and 0.19 respectively. All the measures for this pair in Table 7 record a decrease. However, Panel C in Figure 4 shows the copula between the two cryptocurrencies and suggests that they are still significantly associated.

In summary these measures appear to show that the correlations between the returns on cryptocurrencies and those on the S&P500 Index do show an increase in times of crisis. This supports previous findings by Massoumi and Wu (2021, p1), who report that: “NASDAQ daily return has the most similar density and co-dependence with Bitcoin daily return, generally, but after the COVID-19 outbreak in early 2020, even S&P500 daily return distribution is statistically closely dependent on, and indifferent from Bitcoin daily return”.

4.5. Generalised Measure of Correlation (GMC) Analysis

Table 10 presents the results of the GMC analysis in the two periods, pre and post-COVID-19 and the results matrix reports the cause at the top of the columns and the response along the rows. If we begin with column 2 in Period 1, SPRET, the continuously compounded return on the S&P500 Index, has a negative effect on the Bitcoin return, or GMC of -0.55 and a negative effect on the Ethereum return of -0.73. The third column indicates that the Bitcoin return BITRET, has a negative effect on SPRET of -0.57 and a positive effect on ETRET of 0.83. Finally, the fourth column under ETRET shows that the Ethereum return has a negative effect on SPRET of -0.47, and positive effect on BITRET of 0.80.

Which way does causality run in Table 10? We can look at the coefficients above and below the diagonal in Table 10 and see that SPRET has an effect on BITRET of -0.56, but the effect of BITRET on SPRET is -0.47. Therefore the stronger influence is from the S&P500 to Bitcoin rather than vice-versa, but the causality does run in both directions. Similarly the effect of SPRET on ETRET is -0.73 whilst the effect of ETRET on SPRET is -0.47. Clearly, SPRET has the larger causal impact. Finally we can see that BITRET has an 0.83 effect on ETRET, whilst ETRET has a 0.80 effect on BITRET. So Bitcoin has the slightly stronger causal influence when it is paired with Ethereum.

In the post-COVID-19 period 2 in Table 10, matters change dramatically. For a start all the GMC values have now become positive. This means that the relationship between the returns on the S&P500 Index returns, SPRET, and the two cryptocurrencies, as represented by BITRET and ETRET have increased to 0.69 and 0.68 respectively. Similarly, the influence of the cryptocurrencies on the S&P500 has become positive and greatly increased, as the last two entries in the row adjacent to SPRET are 0.68 and 0.81 respectively, which suggests that ETRET now has the largest impact on SPRET. The two cryptocurrencies have a large but slightly lower influence on one another. BITRET has a 0.77 GMC in relation to ETRET, whereas the influence of ETRET ON BITRET is now 0.72. These values are now slightly lower than the corresponding ones in the first period.

The most remarkable change is the switch in the signs of the relationships between the cryptocurrencies and the S&P500 from negative to positive, which suggests that they do not provide a strong diversification strategy in times of crisis.

Table 10: GMC Analysis**Period 1: Pre-COVID-19**

	SPRET	BITRET	ETRET
SPRET	1.000	-0.4542502	-0.4695773
BITRET	-0.5563881	1.000	0.8003115
ETRET	-0.7299776	0.8324365	1.000

Period 2: Post-COVID-19

	SPRET	BITRET	ETRET
SPRET	1.000	0.6758405	0.8140017
BITRET	0.6898318	1.000	0.7194903
ETRET	0.6840218	0.7671989	1.000

5. Conclusion

The results of the tests of the measures of association between the returns on the S&P500 Index and the returns on these two cryptocurrencies, Bitcoin and Ethereum, in the the pre and post-COVID-19 periods, all tell a similar story, no matter whether linear and parametric measures, or non-linear and non-parametric measures are adopted.

In the pre-COVID-19 period, regression analysis suggests that there is a significant positive association between the two cryptocurrency returns series but no significant relationship with the S&P500 Index returns. Kendall's tau tests of correlation provide a similar set of results. The results change in the post-COVID-19 period and whilst the relationship between the two cryptocurrency returns series remains positive and significant there is now a positive and significant relationship between the returns on both cryptocurrency returns series and the returns on the S&P500 Index. Kendall's tau metric also suggests significant and positive relationships between all three series.

The non-parametric copula analysis of the relationship between the three pairs of series in the first period, tells a similar story, suggesting that there is a significant association between the returns on Bitcoin and Ethereum, but a minimal association between the cryptocurrency returns and those on the S&P500 index. In the second period, the results change notably, and the correlations between the returns on the two cryptocurrencies and those on the S&P500 Index appear to increase markedly.

The GMC analysis suggests a change in the sign of the relationship between the cryptocurrency returns and those on the S&P500 Index, from negative to positive, and a marked increase in their value. The direction of causality also appears to have switched and the strongest causal influence now appears to run from the returns on Ethereum to those on the S&P500 Index.

These changes are quite dramatic and suggest that cryptocurrencies, in the form of Bitcoin and Ethereum, do not provide a strong potential portfolio diversification tool, at least in the context of this particular crisis. A result that is consistent with the findings of Massoumi and Wu (2021), Kristoufek (2020), Conlon et al. (2020), Lahmiri and Bekiros (2020) and Grobys (2021).
