Financial Markets in Times of Stress

Graciela L. Kaminsky

George Washington University

Carmen M. Reinhart*

International Monetary Fund

First draft: January, 25, 2000

This draft: June 27, 2002. A revised version
of this paper was published in:

Journal of Development Economics, Vol. 69 No. 2, December 2002, 451-470.

In this paper, we examine which markets are most synchronized internationally and exhibit the greater extent of comovement. We focus on daily data for four asset markets: bonds, equities, foreign exchange, and domestic money market. Our sample covers thirty-five developed and emerging market countries during 1997-1999. The extent of comovement and responsiveness to external shocks is examined in different ways. To measure the response of these markets to adverse external shocks, we date the peaks in domestic interest rates and bond spreads and the largest daily declines in equity prices and assess the extent of clustering around the same period. We also analyze which markets show evidence of greatest comovement in general, irrespective of whether there are adverse shocks or not.

* This paper was written while Carmen M. Reinhart was a Professor at the University of Maryland. The paper represents the views of the authors and not necessarily those of the institutions with whom they are affiliated. The authors wish to thank Menzie Chinn, Sebastian Edwards, Vincent Reinhart, Roberto Rigobon, Holger Wolf and participants at the NBER's InterAmerican Seminar in Economics for insightful comments and suggestions and Sergio Kurlat, Amine Mati, and Rafael Romeu for excellent research assistance.

I. Introduction

Much has been written about globalization and the greater degree of capital market integration in the past decade. One strand in this vast literature has developed a variety of approaches to test for the extent of capital mobility.¹ Another rapidly-growing branch has attempted to document the incidence of contagion, spillovers, or international propagation of shocks. Often, these studies focussed on the cross-country correlations of asset returns.²

¹ See, for instance, Frankel (1992) and Obstfeld (1995).

² See Dornbusch, Park, and Claessens (2000), for a recent survey.

However, most of this literature has paid little attention to the probable case that not all asset markets are likely to be affected by external shocks in the same manner or equally integrated internationally.^{3 4} Such differentiation in the sensitivity to external shocks or the extent of global integration may arise for several reasons. For instance, Reinhart and Reinhart (1999) provide a simple model where investors have perfect access to the international bond market but bank customers do not. They show that if depositors have access to international capital markets interest rates on deposits will co-move with the international interest rates on bonds, but if borrowers cannot borrow from abroad, lending rates of interest need not covary with the international interest rates on bonds.⁵ Similarly, if a government allows its bonds to be freely traded internationally but has restrictions on the foreign ownership of equities, one would expect that bond yields would be more responsive to external shocks than equity returns. However, market segmentation of these types will not be the only reason why some asset markets may be more sensitive to external shocks than others. While a variety of narratives describing episodes of contagion suggest that speculative attacks on currencies are bunched together across countries, the heterogeneity in exchange rate arrangements and monetary policy across countries would suggest that exchange rates and the Apolicy≅ domestic interest rate are likely to show less covariation across countries than an internationally traded sovereign bond or

³ External shocks may take the form of a rise in international interest rates, an oil shock, or a financial crisis in another country.

⁴ An exception is Hausman and Rigobon (2000).

⁵ Obviously, the opposite is true if borrowers are the ones with access to international capital markets, while depositors do not.

equity.⁶ Foreign investors may play a more prominent role in some markets (i.e., the market for sovereign bonds) which may increase the degree of comovement across countries, since the same decision makers are involved. Along the same lines, equity price indices may have a markedly different industry composition across countries, which may act to dampen comovement with equity markets across international borders. In other words, the domestic idiosyncratic component in some asset markets is greater than in others.

In this paper, we examine which markets are most synchronized internationally and exhibit the greater extent of comovement. We focus on daily data for four asset markets: bonds, equities, foreign exchange, and domestic money market. Our sample covers thirty-five developed and emerging market countries during 1997-1999. The extent of comovement and responsiveness to external shocks is examined in different ways. First, to measure the response of these markets to adverse external shocks, we date the peaks in domestic interest rates and bond spreads and the largest daily declines in equity prices and assess the extent of clustering around the same period. Second, we conduct principal component analysis over the entire sample to analyze which markets show evidence of greatest comovement in general, irrespective of whether there are adverse shocks or not.⁷

⁶ One example is Eichengreen, Rose, and Wyplosz (1995), which analyzes of Europe=s Exchange Rate Mechanism crisis.

⁷ In the working paper version of this paper, we look for volatility spillovers, working with the simplest of the generalized autoregressive conditional heteroskedasticity (GARCH) models to

examine whether there was a marked change in volatility much along the lines of Edwards (1998) and Edwards and Susmel (2000) and (2001).

In the next section, we describe and date the various episodes of regional or global financial turmoil that we study and provide some background on the international setting during our sample period. In Section III, we compare the extent of comovement across countries and the profile of daily volatility in four asset markets--bond, equity, foreign exchange, and domestic money market. Concluding remarks, sprinkled with some policy implications, are presented in Section IV.

II. Episodes and Background

In what follows, we turn our attention to some of the events or shocks that have shaped financial markets in recent years; all these episodes are likely to be familiar to the reader, as these have received considerable attention in the financial press.

1. Asset markets

Shocks may be confined to a single market, such as equities, or may have more far-reaching consequences, simultaneously affecting foreign exchange, domestic money, and the international bond markets. Most often, when a country is mired in a deep financial crisis, all markets are affected; the currency weakens, domestic interest rates rise as expectations are unsettled (this may be compounded if the monetary authorities tighten policy to restore credibility), the terms of borrowing in international capital markets (assuming access is not lost altogether) deteriorates, and other asset prices (i.e., equity and real estate) slide. Volatility increases across the board. Milder periods of turbulence, owing to external developments, may not have such widespread effects. For instance, the period of financial market turbulence around October 27-28, 1997, was nearly global in scope but was largely confined to equity markets. In

the analysis that follows, we will pay particular attention to how the spread of disturbances across countries differs among the four asset markets we study.

2. Events

Table 1 presents a brief chronology of significant events during the January 1, 1997-August 31, 1999 period. The list is not meant to be exhaustive, rather it highlights some of the key episodes we analyze.⁸ In the remainder of this paper, our focus is primarily on four events. In chronological order, they are: the devaluation of the Thai baht on July 2, 1997; the Russian devaluation and default on August 17, 1998; the September 1-2, 1998 stint, during which Malaysia introduced fairly drastic capital control measures (on September 1st) and LTCM issued a letter to its shareholders revealing its precarious condition (on September 2nd); and the recapitalization of LTCM that began on September 23rd, 1998.

While these events are a focal point of our study, there are other episodes that are encompassed in our analysis. These include: the crash of the U.S. equity market and the speculative attack on Hong Kong on October 28, 1997; the evolution of the Korean crisis following the devaluation of the won on November 17, 1997; the closure of Solomon Brothers' bond arbitrage desk on July 6, 1998; the first Wall Street Journal article on the profit pressures on LTCM on July 20, 1998; the inter-FOMC meeting reduction in U.S. interest rates on October 15, 1998; and the Brazilian devaluation on January 13, 1999, which also coincided with rumors

⁸ For a more comprehensive chronology of the events surrounding the Asian crisis the reader is referred to Nouriel Roubini's home page; for a more detailed listing of significant events in the fall of 1998, see Bank of International Settlements (1999); and for a more extensive chronology of capital controls see Edison and Reinhart (2001).

about a possible debt crisis in China.

3. Data and sample

Our data is daily and spans the period beginning on January 1, 1997 through August 31, 1999. Because of the daily frequency of the data, the variables we analyze are confined to financial markets. Specifically, these variables are: the domestic overnight interbank interest rates (whenever possible); the daily return on equities in the local currency taken from local bourse indices;⁹ the percent change in the daily exchange rate versus the dollar or versus the deutschemark (DM);¹⁰ and, the interest rate spreads on bonds that capture the Apricing of risk \cong . For the industrial countries, the interest rate spread is between corporate and sovereign bonds, while for emerging markets the spread is between a sovereign bond and a comparable United States Treasury security. As regards sovereign bonds, we have tried to use the most liquid of these, since bonds that are infrequently traded are not likely to reflect short term shifts in market sentiment. The particulars for all the data used for the thirty-five countries in our sample are provided, along with their respective sources, in the Data Appendix.

The countries in our sample cover more of the mature-to-emerging-market range of experiences. Countries with less developed capital markets and a significant extent of financial repression are not a part of this study, as the focus rests on high-frequency capital market developments. We can classify the sample into five, somewhat arbitrary, seven-country

⁹ More precisely, returns are defined as the percent change in equity prices, as dividend data is not available on a daily frequency.

¹⁰ For all the countries the exchange rate is bilateral against the U.S. dollar. The exceptions are Estonia and the European countries, for which bilateral exchange rates versus the DM are used. The exchange rate is expressed as number of local currency units per dollar or DM; hence, an increase denotes a depreciation. After January 1, 1999, DM quotes are based on a strict translation from euros.

groupings: The G-7 countries, which are comprised of Canada, France, Germany, Italy, Japan, United Kingdom, and the United States; and the transition economies, which include Bulgaria, Czech Republic, Estonia, Hungary, Poland, Russia, and the Ukraine. The remaining three groups are primarily by region. There is the Asian cluster, which includes Hong Kong, Indonesia, Malaysia, the Philippines, Singapore, South Korea, and Thailand. The other European group, which excludes those countries that are part of the G7, and includes, Finland, Greece, Holland, Norway, Spain, Sweden, and the non-European Turkey. Finally, the Latin American sample consists of the larger economies in the region, Argentina, Brazil, Chile, Colombia, Mexico, Peru, and Venezuela.

4. The international setting

Tables 2 and 3 present a broad brush view of the key variables during three sub-periods in our sample: the period in between the devaluation of the Thai baht and that of the Russian ruble; the couple of weeks in between the Russian devaluation and the introduction of capital controls in Malaysia, which occurs a day before LTCM issued a letter to its shareholders; and the stretch between that day and the relatively rare interim easing of monetary policy in the United States. Table 2 presents the cumulative change in the variables of interest, which simply compares the end point to the first observation of the sample. Hence, for example, interest rates were roughly the same on August 17, 1998 as they were on July 1, 1997 for the G7 and the Latin American economies, although, rates were higher for the Asian and transition economies (7.09 and 13.14 percent, respectively.) Since the first sub-sample covers a much longer period, Table 3 presents the same data for daily changes at a monthly rate.¹¹ So, for instance, during the first sub-

¹¹ Specifically, the change reported in Table 3 divided by the number of days in the subsample raised

sample, interest rates rose (on average) by 0.69 percent per month for the transition economies, but the increase was close to zero for the G7 countries.

The three subsamples are quite distinct from one another. Prior to the Russian crisis, Asian exchange rates had depreciated markedly against the US dollar--largely owing to the collapse of the Indonesian rupiah. Asian equity prices fell 56 percent, while the terms at which they could borrow in international capital markets deteriorated, as reflected in the widening of bond spreads of 354 basis points. Over this period, other emerging markets also experienced declining asset prices, despite relatively stable exchange rates and interest rates. For the Latin American group, equity prices fell 32 percent, as equity markets in the region fell across the board.¹² More surprisingly, bond yield spreads widened 522 basis points--even more than for the Asian crisis countries.¹³ The widening in bond spreads is even more pronounced for the transition economies. However, this is largely owing to Russia. Equity markets were falling nearly everywhere for the transition group, with the exception of Hungary. By contrast, most European and G-7 equity markets had substantial rallies during this period, with notable exceptions being Japan (down 25 percent) and Norway (down 11 percent).

to 30 to present it as a monthly rate.

¹² The decline in equity prices was largest for Venezuela (56 percent) and smallest for Colombia (11 percent).

¹³ Again, the largest deterioration was for Venezuelan bonds, as the spread widened by 1,793 basis points.

Following the Russian devaluation and before the LTCM story entered the public domain, the picture changes markedly.¹⁴ Equity markets take a tumble everywhere, with the exceptions of South Korea and Russia, which begins to recover from its massive slide. Latin American markets are particularly hard hit. Bond spreads widen dramatically, especially for Latin American sovereign borrowers. For Russia, the spread widens to more than 6,300 basis points. Bid-ask spreads on debt instruments also widen dramatically, reflecting the loss of market liquidity. As the next section will illustrate in the context a simple model, this reflected several withdrawals from risk-taking. Domestic interest rates in Latin America rise during this period, with Mexico and Peru posting the largest increases. The higher interest rates during this period owe both to the loss of credibility many emerging markets suffered following the Russian default--in part on the reassessment of the likelihood of bailouts by the International Monetary Fund--and to the use of tight-money policies by many emerging market central banks to defend exchange rates.

What is striking about the last subsample, which are the six weeks preceding the Fed=s interest rate cut, is that emerging markets appeared to be recovering already from the Russian shock. Interest rates had started to decline, particularly in Asia, while equity markets were recovering, especially in Malaysia and Thailand. Bond spreads for Latin America had begun to narrow (by about 289 basis points), although yields spreads remained well above pre-crisis levels. For industrial countries the picture is very different from the emerging markets, as equity markets continued to tumble and bond spreads widened further.

¹⁴ It is important to note that stories of LTCM=s financial difficulties were circulating as early as July

This strikingly divergent performance between emerging and mature capital markets in this last period may owe to the fact that, during these weeks, there was much speculation in financial circles, as to whether there would be more LTCMs. Hence, there was concern about the health of the financial centers, rather than the periphery. By then, the periphery had already been hard hit and portfolio inflows of capital (bond and equity) had dramatically dried up. This stands in contrast to the equity market booms most of the industrial countries were enjoying prior to the Russian/LTCM shock.

III. International Comovement in Asset Markets: Some Evidence

To begin our enquiry as to which asset markets show the greatest extent of comovement across countries, we examine some basic descriptive statistics. In particular, we compare the dates of maximum and minimum values during the full sample to those of the episodes we are interested in analyzing. Many of the countries in our sample do not allow their currencies to float freely--even when they say they do.¹⁵ As a consequence, we focus in the overnight domestic interest rate, as the highest rates may be associated with speculative attacks on the foreign exchange market. Table 4, which provides the dates of the maximum values, reveals that, for most of the Asian countries in our sample, interest rate peaks occur in the second half of 1997 and into early 1998, a period of much turbulence in the region.¹⁶ August and September 1998 also shows numerous entries, coinciding with the Russia/LTCM crises.¹⁷ However, with

¹⁵ See Reinhart (2000) and Calvo and Reinhart (2002) on the pervasiveness of the Afear of floating across both industrial and emerging market countries.

¹⁶ This issue will be discussed in more detail in the next section.

¹⁷ When confronted with a common shock that affects the financial center (such as Russia and

only a couple of exceptions, peaks in domestic interest rates are not highly synchronized across countries. This lower degree of comovement could owe to the heterogeneity across countries as regards what money market interest rates reflect or simply because monetary policy responses vary across countries. The global coordination of disturbances is far more evident in Tables 5 and 6, which provide the dates of the largest daily equity market declines and the largest increase in the bond yield spread. These equity market crashes are overwhelmingly clustered on October 27-28, 1997 and in the interval between the Russian devaluation and the Federal Reserve's intermeeting interest rate cut. The bunching of disturbances across countries is even more evident in the bond spread data presented in Table 6. With a few exceptions, the largest daily increases occur in the late summer and fall of 1998.

On the basis of these simple observations, it would appear that the October 1997 disturbance, while far-reaching in its global scope was, confined to equity markets, while the August-October 1998 disturbances extended to bond markets as well.

1. Principal component analysis

To assess more formally how the degree of comovement across countries in several financial variables evolves over time and across regions, we applied principal component analysis to the financial time series data over the full sample, as well as several subsamples.

We focus on four daily time series, the domestic policy interest rate, the return on equity, the change in the exchange rate (in percent), and the bond spreads, for thirty-four of the thirty-

LTCM), A fear of floating \cong (if not an explicit peg) may also bring about a synchronized rise in domestic interest rates, as central banks tighten in an effort to cap the slide in the currency (see Calvo and Reinhart, 2002).

five countries in our.¹⁸ From these series, we constructed a smaller set of series, the principal components, that explain as much of the variance of the original series as possible. The higher the degree of co-movement in the original series, the fewer the number of principal components needed to explain a large portion of the variance of the original series. In case where the original series are identical (perfectly collinear), the first principal component would explain 100 percent of the variation in the original series. Alternatively, if the series are orthogonal to one another, it would take as many principal components as there are series to explain all the variance in the original series. In that case, no advantage would be gained by looking at common factors, as none exist.

The procedure begins by standardizing the variables so that each series has a zero mean and a unit standard deviation. This standardization ensures that all series receive equal treatment and the construction of the principal component indices is not influenced disproportionately by the series exhibiting the largest variation. The correlation matrix of the standardized series is decomposed into its Eigen-vectors and the diagonal matrix of Eigen-values.

¹⁸ Owing to limited data availability, Bulgaria is excluded from the sample.

The Eigen-vectors are the loading factors, or weights, attached to each of the original series. For a particular time-series, the higher the degree of comovement with other series the higher (in absolute value) its loading factor. If a particular time series is uncorrelated with the remaining series included in the analysis, then its loading factor in the first principal component should be close to zero. A priori, this is what we should expect to see for the time series of, say, a small country with a perfectly idiosyncratic shock, or for a country which has binding capital controls.¹⁹

The results are presented in Tables 7-8 for the four regional groupings and for the G-7 countries. The share of the variance of the original series (in this case equity returns) explained by the first principal component ranges from a low of 0.36 for the transition economies to a high of 0.57 percent for the European group--with the other groups falling in between. These results are hardly surprising, in light of the lack of homogeneity in the Transition economies group relative to the higher degree of integration in Europe.

Examining the factor loadings by region or group, the outcomes are equally intuitive.

¹⁹ As the controls insulate the country from external disturbances (see Edison and Reinhart, 2001).

Among the Asian countries in our sample (Japan excluded), South Korea has the lowest factor loading (0.24); this result is not surprising, given that its own financial crisis began months after the onset of turmoil in Thailand, Indonesia, Malaysia, and the Philippines.²⁰ Malaysia shows the next-to-least degree of comovement (the loading factor is 0.32)--then again, Malaysia had capital controls throughout the latter part of the sample. Among the European grouping, the extent of comovement is the least for Turkey, which has unresolved chronic inflation problems, and Greece. Among the G-7 countries, the patterns of comovement are also largely defined along regions. The four European countries move in unison, the United States and Canada move in another block,²¹ and Japan shows the least comovement with the other G-7 countries.

Turning to Latin America, comovement is strongest among the larger three--Argentina, Brazil and Mexico, and least for Colombia and Venezuela. These patterns of covariation are not unique to the 1997-1999 sample. In the immediate aftermath of the Mexican crisis, when most Latin American equity markets posted substantial declines, Colombia=s equity market posted moderate gains.²² Lastly, comovement is strongest among the earlier reformers--Poland, the Czech Republic, and Hungary--and weakest the Republics of the former Soviet Union.

Tables 7 and 8 also report, for comparison purposes, the results for interest rate changes and exchange rates. As is evident for all the country groups, the extent of covariation is noticeably lower reaching 0.4 for any group=s exchange rates and interest rates.

²⁰ See Kaminsky and Reinhart (2001) for an analysis of the interdependence of the Asian economies before and after the 1997 crisis.

²¹ This is evident in the factor loadings of the second principal component, shown in the next column.

²² See Calvo and Reinhart (1996) for an analysis of this episode.

2. *Conditional variances*

In this section, we work with the simplest of the generalized autoregressive conditional heteroskedasticity (GARCH) models to examine whether there was a marked change in volatility during and around the various episodes analyzed in the preceding section.²³ To economize on space, we only summarize our findings, which are reported in greater detail in the working paper

$$r_t = \sum_{i=1}^k \beta_i r_{t-i} + \varepsilon_t$$

$$\sigma_{rt}^2 = \omega + \alpha \varepsilon_{t-1}^2 + \delta \sigma_{t-1}^2$$

version of this paper. We consider the following models:

²³ In all cases a GARCH (1, 1) model was estimated.

where stock returns are denoted by r_t , in equation (1), and the random shock is denoted by ε .²⁴

In the variance equation, ω is the mean of the variance; the lag of the mean squared residual from the mean equation (i.e., ε^2_{t-1}) is the ARCH term and last period's forecast variance (i.e., σ^2_{t-1}) is the GARCH term. The number of autoregressive lags, k , was selected on a country-by-country basis using both the Akaike and Schwartz criteria; if these yielded different results as regards the optimal lag length, both models were estimated. We also estimated a comparable model for the domestic interest rate and the change (in percent) of the exchange rate. Periods of turbulence that are part of our sample of daily observations render the assumption of identically and independently distributed conditionally normal disturbances in the most basic GARCH model inadequate.²⁵ Given the presence of heteroskedastic disturbances in our sample (i.e., the ε s), we use the methods described in Bollerslev and Wooldridge (1992) to compute the Quasi-Maximum Likelihood covariances and standard errors.

²⁴ More precisely, the variable in question is capital gains or losses, as there is no dividend data at a daily frequency.

²⁵ For a discussion of some of the implications of changes in the variance of economic fundamentals during crises periods in the analysis of the international transmission of shocks, see Forbes and Rigobon (1998).

Before turning to a discussion of specific countries, however, there are some general patterns that emerge from the analysis of the conditional variance of equity returns for these thirty three countries that merit mention.²⁶ Even without knowing what events transpired during the three years covered in our sample, the equity returns data reveal four periods of general market stress, as reflected in large-to-moderate spikes in the variance of equity returns. Two periods stand out most clearly from a review of the figures: a marked period of turbulence at end-October-early November of 1997 in most of the equity markets in our sample--this episode was, for the most part, relatively short-lived; and a more severe and far more protracted bout of volatility that, for most countries, begins in August of 1998 and lasts through October of that year.²⁷ Indeed, in more than half of the countries in the sample the largest spikes in volatility were recorded in the late summer and fall of 1998 and, that in nineteen of the thirty-three countries, this period was associated with the most persistent bout of volatility in the sample.

In addition to the two more obvious episodes of market volatility on a global scale, there are two periods of market stress which merit discussion. The first of these occurs in early 1998, at the height of the Asian crisis and it engulfs all the Asian countries in our sample, including Japan.²⁸ Indeed, for seven of the countries in our sample (all in Asia), this episode shows the most marked and persistent rise in equity market volatility. The high volatility during this

²⁶ The conditional variance of daily equity returns is plotted for each country in Appendix Figures 1-18, and Tables 17-21 in the working paper version of this paper.

²⁷ The first of these episodes lines up with the equity market crash in New York and, particularly Hong Kong on October 28, 1997, while the second spans the Russian crisis-LTCM debacle.

²⁸ Korea's devaluation of the won occurs on November 17 and their negotiations with the International Monetary Fund last into late December 1997-early January 1998. Furthermore, during this period there are recurring rumors that China will devalue and set the stage for a new round of financial instability in the region.

period, however, is largely confined to Asia, as both mature and emerging markets elsewhere are relatively tranquil. The other market turbulence episode revealed by this data occurs in January 1999, and it is most evident in Latin America. The equity markets of four countries in our sample (all in Latin America) record their largest spike in volatility in that month; the shock, however, seems to be relatively short-lived. Several European and Transition economies= equity markets also show more moderate increases in volatility. This spike corresponds to both the Brazilian devaluation of the real and several market disruptions after the Chinese government refused to help foreign creditors of GITIC. Fears of debt crisis in China also swept through Hong Kong at this time.

As regards individual countries, it is worth noting that in some cases overlap with Aglobal events≡ may be more of a coincidence than the conditional variances reveal. For example, as discussed earlier in the context of the principal component analysis, Colombia is a country whose equity market shows little comovement with the rest of Latin America or other equity markets. Its deep financial crisis, which occurs shortly after the devaluation of the ruble, had little to do with Russia or LTCM--as it had been brewing for fundamental reasons for some time. Similarly, the spike in interest rates in Greece following the equity market turbulence in end-October 1997, was owing to an attack on the drachma motivated by predominantly domestic considerations. Another feature of the conditional variances, which applies to several Acrisis≡ countries, is that the conditional volatility of equity returns remains consistently higher in the post-crisis period. This is most evident of Indonesia and South Korea, but it also applies to Colombia, the Philippines, and Thailand. In sum, the analysis of the variance of equity prices provides additional support that disturbances have an important global dimension in the period

under scrutiny. Far more so than what is observed in foreign exchange and money markets.

VI. Concluding Comments

This paper has presented evidence to suggest that there are important differences in the responsiveness to external shocks and, more broadly, in the extent of international synchronization across asset categories. Hence, the implications that one can draw about the extent of globalization and the degree of capital market integration depends importantly on which is the market examined. With the exception of the G-7, which includes heterogeneous cycles among the United States and Canada, Europe, and Japan, bond yield spreads exhibit--by far--the highest degree of comovement both across countries for the entire sample and various subsamples.²⁹ One can speculate that, given that these spreads are dominated by sovereign risk, they represent a more homogeneous asset class than the equity, currency and, money market counterparts--sovereign bonds may also have a more common and homogeneous foreign investor base. A distant second in the extent of comovement in returns (again, the exception being the G-7 group) are equity markets; for the G-7 countries, however, equity markets are the most correlated of the four asset markets we examine. Furthermore, in terms synchronicity, as measured by the overlap of dates in which the largest declines were observed, equity markets also show substantial responsiveness to external shocks.

For nearly all the regions or country groupings, the exchange rate market, followed bonds and equities (in that order) as the most correlated across countries. The policy interest rate, not surprisingly--given the heterogeneity across countries in monetary policy and the extent of

²⁹ Not all of these are reported here, but the results are available from the authors upon request.

credibility--comes as a distant fourth in terms of international comovement. Idiosyncratic domestic shocks appear to be the dominant factor in explaining their behavior.

In sum, studying the extent of capital mobility and the impacts of external shocks has been most often too limited to focussing on a particular asset market. Our results taken together suggest that even countries with little capital account restrictions may be subject to other forms of capital market segmentation. Hence, the differences in the degree of capital mobility is something that not only needs to be understood across countries, but across markets in a particular country as well.

Appendix Table 1: Construction of spreads

Given availability of data, spreads were either constructed with respect to a corporate bond or with respect to government bonds (US or German). Here is a breakdown of spreads used

Countries	Spread Construction
Greece	Spread between Greek government bond and German government bond (DM)
Canada, France, Germany, Italy, UK, US, Spain	Spread between local government bonds and respective corporate bonds (local currency)
All other countries	Spread between local government bonds and US government bond (US\$)
