Abstract

The flattening of the world thanks to the cluster of profound socio-economic and politico-cultural changes has created unprecedented challenges for organizational leadership and management. The fast evolving global world of ours where challenges have to be continually met requires timely decision taken by CEOs’ (Chief Executive Officers) who shape and give direction to world politics and economic order. In the light of this we have studied the decisions taken by CEOs’ of goods producing firms’ and their decisions on firm’s productivity and profitability which in turn depend to a great deal on CEOs’ salary structure. Better salary leads to influx of people from all over the world often leading to brain drain situation in developing countries. Globalization has created social disparities in the present economic system that are molded by the increasing polarization of work between people working in high paid knowledge sectors and others working in low paid sectors. Prior research has suggested that in a global environment capitalists benefit from other capitalists who pay higher salaries from the expansion of income.

The salary data of 177 CEOs’ (Chief Executive Officers) for the year 1990 – published in the Business Week of June 6, 1991 has been analyzed to determine and correlate the effects of sales, market value (mktval), profit and CEOs’ tenure (ceoten) on the CEOs’ salary.

The performance of goods producing firms where the CEOs’ served has been found to be strongly correlated with their salary intakes. The basic purpose of this research and study is to analyze the deciding factor in the salaries of top executives.

The CEOs’ are the policy makers in all government and non-governmental organizations and their decision-taking greatly influences the performances of their institution. CEOs’ performance with respect to their salaries and other variables mentioned above is found to be the deciding factor as regards policy execution matters in goods producing firm’s performances.

Keywords: Econometric model, multicollinearity, STATA, elasticity, employment tenure and market value.

JEL Classification: C1; C2; C8; D1; J2; L1
1. INTRODUCTION

Our research is based on the data [1] consisting of 177 CEOs’. The data was used to examine the effects of CEOs’ salary upon goods producing firm’s performance. Initially different variables were taken which explained the impact of annual salary of CEOs, on the goods producing firm’s sales, market value, profit and CEOs tenure. The data was recorded in 1990, so cross sectional data\(^1\) [2] is available.

Regression model of salary was built with different explanatory variables in order to see if we incorporate certain explanatory variables, what the effect shall be. Do those variables explain well the regressand (dependent variables) or not and whether these are appropriate, and if not, how can they be made suitable? In some cases we took log of certain variables where we could not obtain linear relationship. This was done to find out the stochastic relationship existing between certain variables. There are several other issues related to the relationship between the variables which is left open for further research. The inference (the estimation and testing of hypothesis) is the other important aspect of our research which contributes to the other significant facet of our analysis.

2. THE MODEL

The relationship between annual salary\(^2\), firm’s sales\(^3\) and market value\(^4\) is assessed through computation using STATA\(^10\) [3]. Scatter diagram was applied to study the causal relationship between different variables. If we look at Fig. 1 shows that the red points\(^5\) are not appropriately lying around the straight line and more or less same state is of the blue points\(^6\). The variables were then plugged with log so that the scatter plot could be transformed into linear shape as shown in Fig. 2. As seen now in Fig. 2 the red points and blue points are lying almost about the straight line. Therefore, after experimenting it was concluded that the behavior of the log variables was linear in nature.

\(^1\) Data are recorded in single point of time.
\(^2\) 1990 compensation; assessed in thousands of dollars.
\(^3\) 1990 firm sales; assessed in millions of dollars.
\(^4\) Market value at the end of year 1990 assessed in millions of dollars.
\(^5\) Showing the points of market value with salary.
\(^6\) Showing the points of sales with salary.
Salary = $\beta_1 (sales)^{\beta_2} (mktval)^{\beta_3} e^u$ \hspace{1cm} (1)

Afterwards the above exponential regression model was converted into the log-log model as shown in equation 2.

$log(Salary) = \log(\beta_1) + \beta_2 \log(sales) + \beta_3 \log(mktval) + u$ \hspace{1cm} (2)

The disturbance term $u$ is assumed to follow normal distribution with mean 0 and variance $\sigma^2$. $\beta_2$ is the elasticity of salary with respect to sales and $\beta_3$ is the elasticity of salary with respect to market value. $\beta_1^* = \ln(\beta_1)$ in the model and is formulated as:

$log(Salary) = \beta_1^* + \beta_2 \log(sales) + \beta_3 \log(mktval) + u$ \hspace{1cm} (3)
Output of the fitted above log-log model (constant elasticity model) is:

```
. regress lsalary lsales lmktpval
              Source |        SS       df       MS              Number of obs =     177

------------------------------------------------------------------------------
```

Table 1

The intercept value 4.621 represents the estimate of $\beta_1 (\ln \beta_1)$ i.e. $\hat{\beta}_1 = 4.62$, value of elasticity of salary with respect to sales is 0.162 and represents the estimate of $\beta_2$ i.e. $\hat{\beta}_2 = 0.162$, and the value of elasticity of salary with respect to market value is .107 representing the estimate of $\beta_3$ i.e. $\hat{\beta}_3 = 0.107$, as shown in Table 1. Therefore, the fitted regression model is as follows.

$$\ln(\text{Salary}) = 4.621 + 0.162 \ln(\text{Sales}) + 0.107 \ln(\text{mktval})$$  \hspace{1cm} (4)

In order to find the estimate of exponential regression model we computed the value of $\beta_1 (e^{\hat{\beta}_1})$ and got $\beta_1 = 101.6$. Therefore,

$$\text{Salary} = 101.6 \times (\text{Sales})^{0.162} \times (\text{mktval})^{0.107}$$  \hspace{1cm} (5)

Consequently for interpretation of the model, the fitted model given in equation 4 is considered.

3. METHODOLOGY

Scatter diagram of CEOs’ salary was constructed with respect to sales and market value as they were found to be the most salary-influencing variable factors. The scatter diagram showed that the points were not lying around a straight line, and, therefore, logged variables had to be used, with which it was seen that more or less all points were lying along a straight line, and this required log-log or constant elasticity model for regression.
In this paper statistical inference approach was adopted to test the parameter connotation, and the overall significance of the model was checked through ANOVA. For determining the coefficient of determination of the model, we plugged from time to time one variable after the other; like profit and CEOs tenure. As more and more of the above variables were incorporated it was seen that corresponding increases in the value of coefficient of determination took place. Correlation matrix technique was applied to locate multicollinearity amongst regressors. Combined matrix scatter plot was used to observe the presence of multicollinearity amid explanatory variables. To locate whether or not high or low degree of multicollinearity persisted in our model, VIF (variance inflation factor) and TOL (tolerance) mathematical testing methods were used. CI (condition index) procedure based on extreme Eigen-values was incorporated to check whether at this stage in the model serious collinearity problem existed or not. Hence, Ramsey’s RESET (Regression Specification Error Test) was fruitfully used to examine whether or not certain variables within the model should be omitted and at the same time ensure that the selected variables are specified as per the given specification and appropriately incorporated. Graphical approach (histogram and Q-Q plot) was used in order to see normality of the disturbance term which was the requirement for latter test done in our research. Finally at the end Breusch-Pagan/Cook-Weisberg test was successfully carried out to find the presence of heteroscedasticity in the fitted values of the final model built. Our inference was found to be correct and logically true. Throughout the work OLS (ordinary least square) technique was used as a standard. The basic purpose was to locate which variable has a lasting effect on the CEOs’ salary. Goods producing firm’s Sales clearly had the greatest influence on CEOs’ salary as compared to the rest of the explanatory variables taken.

3.1 INTERPRETATION OF THE FITTED MODEL

As far as the given model is concerned, the partial regression coefficients represents the elasticity, where \( \hat{\beta}_2 = 0.162 \) tell us that if there is one percent increases in goods producing firm’s sales, CEOs’ salary is increased by about 0.162 %, if market value taking as a constant. Similarly, \( \hat{\beta}_3 = 0.107 \) explains that if one percent increase in market value is estimated it increases CEOs’ salary by about 0.107 % keeping goods producing firm’s annual sales as a constant.
3.2 SIGNIFICANCE OF ELASTICITY

If we look into the significance of elasticity we will see whether the elasticity of salary with respect to sales i.e. $\beta_2$ is significant and if the elasticity of salary with respect to sales i.e. $\beta_3$ is significant too. The P-value approach is used to test the significance of elasticity. The P-value of corresponding partial regression coefficient has been taken from the Table 1. As seen in Table 2 partial regression coefficients are significant, since the explanatory variables after taking the log are explained by the regressand (salary) better than before the application of log. Regressors are found to be linearly related to the response variable.

<td>0.00$^*$</td>
<td>0.025</td>
<td>Significant</td>
</tr>
<tr>
<td>$\beta_3$</td>
<td>$\beta_3 = 0$ or Insignificant</td>
<td>$\beta_2 \neq 0$ or Significant</td>
<td>0.035$^{**}$</td>
<td>0.025</td>
<td>Significant</td>
</tr>
</tbody>
</table>

Table 2

- Policy: if P-value > Level of Significance, accept null hypothesis, otherwise reject null hypothesis.
- * Represents the P-value of t-statistic which is used to test the elasticity of salary with respect to sales keeping market value as a constant.
- ** Represents the P-value of t-statistic which is used to test the elasticity of salary with respect to market value keeping sales as a constant.
- Level of significance is checked at 5%.

3.3 OVERALL SIGNIFICANCE OF THE MODEL

The overall significance of the model is tested through F-test or P-value approach. The P-value of F-statistic is taken from Table-1, after using the software STATA$^{10}$.

<table>
<thead>
<tr>
<th>Null Hypothesis</th>
<th>Alternate Hypothesis</th>
<th>P-value</th>
<th>Level of Significance</th>
<th>Decision</th>
</tr>
</thead>
<tbody>
<tr>
<td>$\beta_2 = \beta_3 = 0$ or Insignificant</td>
<td>Not all partial regression coefficients are simultaneously zero or Significant</td>
<td>0.00$^{***}$</td>
<td>0.05</td>
<td>Significant</td>
</tr>
</tbody>
</table>

Table 3

- Policy: If P-value > Level of Significance, accept null hypothesis, otherwise reject null hypothesis.
- $^{***}$ Represents the P-value of F-statistic which is used to test overall significance of the model.
- Level of significance is checked at 5%.
The P-value = $P(F \geq 37.13) \equiv 0$ which is less than the level of significance leads to the rejection of the null hypothesis. Since not all partial regression coefficients are simultaneously zero, therefore taking $\log(sales)$ and $\log(market\ value)$ together have an effect on $\log(salary)$. We, therefore, conclude that the model is overall significant.

3.4 PLUGGING OF FURTHER VARIABLES

As we know that CEOs salary not only depends on the goods producing firm’s sales and market values as several other variables also do affect CEOs salary. So, other variables are incorporated into the model (2).

3.4.1 PLUGGING THE ‘PROFIT’ VARIABLE INTO THE MODEL

Profit$^7$ is another variable that has impact on CEOs’ salary. Profit was not incorporated in logarithmic form because the profits for nine of the companies/institution in the data are negative. Therefore the variable Profit was plugged into the model given in equation 3 without logarithmic form, and fitting again the above model yields:

$$ \log(Salary) = \hat{\beta}_1 + \hat{\beta}_2 \log(sales) + \hat{\beta}_3 \log(mktval) + \hat{\beta}_4 \text{profits} + u $$

(6)

</table>

Fitted regression equation can now be written as:

$$ \hat{\log}(Salary) = 4.69 + 0.161 \log(sales) + 0.098 \log(mktval) + 0.000036 \text{Profit} $$

(7)

$^7$ 1990 profit assessed in millions of dollars.
In the above model the coefficient on profit is very small. It is to be noted that profit is measured in millions, so if profit increase by $1 billion, implying change in profit is equal to 1,000. This is a huge change indeed, meaning that an increase in predicted salary is only about 3.6%. However, it should be noted that in the model we are holding sales and market value as fixed. Then the question arises that whether these institution performance variables explain most of the variation in CEOs’ salary or not. The answer is that, taken together, these variables (and dropping profit does not change result much) do explain almost 30% (see $R^2$ in Table 4) of the variation in log(salary). However, this does not explain “most” of the variation because certainly there must be other factors which do also affect CEOs’ salary.

### 3.4.2 PLUGING OF THE “CEOs TENURE” INTO THE MODEL

Now incorporating the fourth variable i.e. CEOs tenure\(^8\) into the model (3), we get:

\[
\log(Salary) = \beta_1 + \beta_2 \log(sales) + \beta_3 \log(mktval) + \beta_4 \text{profits} + \beta_4 \text{ceoten} + u
\]  

\(8\) Tenure of CEOs at firm’s/organization.

With the help of Table 5 now we can write the fitted regression model as:

\[
\log(Salary) = 4.56 + 0.162 \log(sales) + 0.102 \log(mktval) + 0.000029 \text{Profits} + 0.017 \text{ceoten} \quad (9)
\]

The partial regression coefficient of CEOs’ tenure represents that if one more year CEOs’ tenure increases one more year the predicted salary will increase by more or less 1.2%. The problem is that whether the CEOs’ tenure variable affects the CEOs’ salary variable. The answer can be
provided through the computed value of $R^2$ (shown in Table 5) which explains that almost 32% variations has been explained by plugging all the four explanatory variables from the CEOs’ salary. The point to be noted here is that before incorporating the CEOs’ tenure variable the explained variation was 30%, but after plugging CEOs’ tenure variable only about 2% variations was further explained in regressand.

This again proves that model is overall significant because the P-value of F-statistic is zero, less than the level of significance, as well as, all the partial regression coefficients are significant.

3.5 DETECTION OF MULTICOLLINEARITY

Multicollinearity is a linear relation between many independent variables [4]. multicollinearity has many affects on regression analysis; if multicollinearity exists then OLS (ordinary least square) estimates of the model would not be reliable and its variances may be high. Due to this, the model cannot provide meaningful results for which the model is being built and for the said reasons we are applying the following methods to detect the multicollinearity.

3.5.1 CORRELATION BETWEEN THE VARIABLES

However, some questions may be raised here: Are the independent variables correlated to each other and whether the multicollinearity assumption violates. For validating purposes we construct correlation matrix.

<table>
<thead>
<tr>
<th>lsalary</th>

</tr>
<tr>
<td>ceoten</td>
<td>0.1147</td>
<td>-0.0377</td>
<td>-0.0435</td>
<td>-0.0216</td>
</tr>
</tbody>
</table>

Table 6

We are finding the sample correlation to detect the multicollinearity amongst the independent variables. The correlation between log(sales) and log(market value) is about 0.74(approx.), between log(sales) and profit is about 0.61(approx.), and between log(market value) and profit is
about 0.78, which are fairly high. On the other side the correlation of \( \log(\text{sales}) \), \( \log(\text{market value}) \) and profit with CEOs tenure is too small (negligible) but negative. This means that CEOs tenure does not have much multicollinearity with other variables.

However, from the above we cannot be certain that multicollinearity is not a big problem amongst the above explanatory variables, so therefore we apply other techniques such as detection of multicollinearity through scatter plot.

### 3.5.2 DETECTION OF MULTICOLLINEARITY BY SCATTER PLOT

Scatter plot was applied to see how the variables in the given regression model are related. Fig. 3 represents the scatter plot for the CEOs’ salary. This is a five-by-five box diagrams because we have five variables in the model, a dependent variable \( \log(\text{salary}) \) (lsalary) and four explanatory variables: \( \log(\text{sales}) \) (lsales), \( \log(\text{market value}) \) (lmktval), profit, CEOs’ tenure (ceoten). There are no scatter points in the boxes from the main diagonal starting from the upper left-hand corner and going to the lower right-hand corner. The leading diagonal shows the correlation coefficient of itself which is always equal to 1. The off-diagonal shows inter-correlations among the given variables. The variables \( \log(\text{sales}) \) (lsales) and \( \log(\text{market value}) \) (lmktval) are correlated (the correlation coefficient between the two is 0.7359). The variables \( \log(\text{sales}) \) (lsales) and profit are correlated (the correlation coefficient between the two is 0.6063). The variables \( \log(\text{sales}) \) (lsales) and CEOs’ tenure (ceoten) are very small and negatively correlated (the correlation coefficient between the two is -0.0377). The variables \( \log(\text{market value}) \) (lmktval) and profit are correlated (the correlation coefficient between the two is 0.7769). The variables \( \log(\text{market value}) \) (lmktval) and CEOs’ tenure (ceoten) are very small and negatively correlated (the correlation coefficient between the two is -0.0435). The variables, profit and CEOs’ tenure (ceoten), are very small and negatively correlated (the correlation coefficient between the two is -0.0216).

The same obtained above mathematical evaluation for correlation can be graphically verified from the matrix scatter plot as shown below.
Fig. 3

Moderate linear relationship is observed through above multiple scatter plots if we look at row 3 and column 2. Row 4 and column 2 suggest low moderate linear correlation. Row 4 and column 3 also represent low moderate linear correlation. Row 5 and column 2 suggest almost no linear correlation and similarly row 5 and column 3 suggest almost no linear correlation and similar condition is of row 5 and column 4.

From the above analysis it cannot be surely said that multicollinearity does not exist and therefore the following mathematical testing methods were applied to arrive to a concrete conclusion.

3.5.3 VARIANCE INFLATION FACTOR AND TOLERANCE

The strength of multicollinearity as well as the speed with which variances and covariances increase is measured by the variance inflation factor (VIF)[5][6]. The formula applied for VIF is:

\[ VIF_j = \frac{1}{1 - R_j^2} \quad ; \quad j = 1, 2, \ldots, k \]
Where $R_j^2$ is the coefficient of determination the regression of the $j^{th}$ independent variable on the remaining $(k - 1)$ independent variables.

Tolerance [8] is nothing but the inverse of VIF. The tolerance is computed as:

$$TOL_j = \frac{1}{VIF_j}; \quad j = 1, 2, \ldots, k$$

Policy-I: \[
\begin{align*}
&\text{The variable is highly collinear} & \text{if VIF} & > 10 \\
&\text{The variable is not highly collinear} & \text{if VIF} & \leq 10
\end{align*}
\]

and

Policy-II: \[
\begin{align*}
&\text{The variable has insignificantly greater degree of collinearity} & \text{if TOL} & \to 0 \\
&\text{The variable has significantly less degree of collinearity} & \text{if TOL} & \to 1
\end{align*}
\]

Above Policy-I and Policy-II has been formulated from Gujarati, D. N. (2009), *Basic Econometrics* (5th edit.), p. 340.

Table-8

- **** Represent that Rankings are in ascending order i.e. the variable having least strength of multicollinearity has been assigned rank 1 accordingly and so on.
It has been found that according to formulated Decision-I and Decision-II as per policies I & II respectively high multicollinearity does not exist among the variables. According to Table-8 CEOs tenure (ceoten) has least multicollinearity and log-market value (lmktval) is the most multicollinear as compared to all other explanatory variables taken. The variables profit and log-sales in terms of multicollinearity hold second and third positions respectively. For further refinement of our result the following condition index procedure has been utilized.

3.5.4 DETECTION OF MULTICOLLINEARITY THROUGH CONDITION INDEX (CI) BASED ON EXTREME EIGEN VALUES

To diagnose the multicollinearity between the regressor, the technique of condition index (CI) is reliable which is based on Eigen values, the condition index would be found as:

$$ CI = \sqrt{\frac{\text{Maximum eigen value}}{\text{Minimum eigen value}}} = \sqrt{k} ; \quad \text{where } k \text{ is the condition number} $$

Policy-III: \[ \begin{align*} \text{There is weak multicolinearity} & \quad \text{if } CI < 10 \\ \text{There is moderate to strong multicolinearity} & \quad \text{if } 10 \leq CI \leq 30 \\ \text{There is severe multicolinearity} & \quad \text{if } CI > 30 \end{align*} \]

Policy-III has also been formulated from Gujarati, D. N. (2009), *Basic Econometrics* (5th Ed.), P.340.

</tbody>
</table>

Table 9
We have maximum and minimum Eigen values 2.41678 and 0.188562 from table 9 respectively so therefore,

\[ k = \frac{2.41678}{0.188562} = 12.8169 \]

Then, \( CI = \sqrt{k} = \sqrt{12.8169} = 3.58007 \)

According to policy-III we observed that CI (condition index) is less than 10 so it suggests that there is weak multicollinearity or we can say in short that we do not have a serious collinearity problem. It means our model (9) has passed the multicollinearity issue in positive aspect. Using Q-Q plot and histogram it was found that residuals follow normal distribution.

### 3.7 RAMSEY’S REGRESSION SPECIFICATION ERROR TEST

Ramsey (1969) gave nevertheless another technique for testing a model’s specification. The validation for the Ramsey RESET method is that the estimated residuals (\( \hat{u} \)) that stand for omitted-variable effects can be estimated by a linear combination of the powers of the fitted values [10].

```
. estat ovtest
```

| Ramsey RESET test using powers of the fitted values of |salary
<table>
<thead>
<tr>
<th></th>
<th></th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>Ho: model has no omitted variables</td>
<td>F(3, 169) = 1.08</td>
<td>Prob &gt; F = 0.3588</td>
</tr>
</tbody>
</table>

<p>| Table 10 |
|---------------------------------|---------------------------------|--------------------------------|</p>
<table>
<thead>
<tr>
<th>Null Hypothesis</th>
<th>Alternate Hypothesis</th>
<th>P-value of F-statistic</th>
<th>Level of Significance</th>
<th>Decision</th>
</tr>
</thead>
<tbody>
<tr>
<td>The model has no specification error</td>
<td>The model has specification error</td>
<td>0.3588****</td>
<td>0.05</td>
<td>Significant</td>
</tr>
</tbody>
</table>

| Table 11 |
|---------------------------------|---------------------------------|--------------------------------|
| Policy: if P-value > Level of Significance, accept null hypothesis, otherwise reject null hypothesis. |
| ***** Represents the P-value of F-statistic is used to test specification error of fitted model. |
| Level of significance is checked as 5%. |

The p-value=\( P(F > 1.68) \approx 0.3588 \) which is greater than the level of significance leads to the acceptance of the null hypothesis. The result shows that the model given in equation 9 has no specification error.
3.8 BREUSCH-PAGAN TEST FOR HETEROSCEDASTICITY

The Breusch-Pagan\(^9\) test for heteroscedasticity of fitted values of regressand is similar to the white test, with an auxiliary regression of the squared OLS (ordinary least square) residuals on variables thought to determine the heteroscedasticity [11]. The BP version of the test the disturbance term is assumed to be normally distributed. For this we have checked the normality in previous work.

```
estat hettest
Breusch-Pagan / Cook-Weisberg test for heteroskedasticity
   Ho: Constant variance
   Variables: fitted values of lsalary
   chi2(1)      =     0.22
   Prob > chi2  =   0.6355
```

Table 12
Tested against 5% level of significance.

From the Table 12 above we can see that the P-value of Chi-square statistic which is used to test the homogeneity of variances of fitted values of log-salary (regressand) here is 0.6355 which is greater than the level of significance according to the P-value approach. Therefore we safely conclude that there is no heteroscedasticity into the fitted values of the model.

4. CONCLUSION

The purpose of this research was to determine the deciding factor behind CEO's salary structure. Of course the major variables in the model were supposed to have major influence on CEO's salary. Indeed some variables have more influence as compared to others.

It has been found that the changing patterns of sales are the most dominant factor amongst all other variables which directly bear on the salary structure of the CEOs’. Secondly, market value directly affects CEO's salary as modern market structure depends on demand and supply of the product in question. Third, it is the experience of the CEOs’ that really matters and their expertise has an impact on the goods producing firm’s performance. Profit, the fourth variable, does not much influence the salary structure as such.

\(^9\) Breusch-Pagan test states an form of heteroscedasticity which arises when the disturbance variance are systematically related to a variable or variables.
In all the combined effect of all the variables like age, college education, profit margins, company’s tenure also influences CEOs salary structure but the effect is negligible. As the influence of these other variables not taken are minor as compared to major variables taken, therefore, we have not computed their values.

In our constructed final model (9) we can confidently say that our model is overall significant where the coefficients of the explanatory variables are significantly stable as well, and all the variables through statistical testing are observed not to be perfectly related to each other, i.e. they have no significant multicollinearity. Same result was also obtained through SAS software.

Heteroscedasticity is not found to be present in the fitted values of salary which shows that the estimates of the model do not have much variability and in short we can say that variances are homogeneous.

Likewise, we may also conclude that the intercept term of the model i.e., salary, must be paid to CEOs’ in order to run an institution whether or not other variables coefficients do or do not influence the salary.

The above model satisfies as well the assumption of regression model.

At the heart of globalization lies the organization of production and distribution of goods and services on a world scale and it is a fact that the dynamics of these depends on CEOs’ value judgment. In a global environment it is the CEO of any firm, multinational or president of government or non-governmental organization who guides the organizations to success. Thus fixation of CEOs’ salary structure plays a pivotal role in a global competitive environment where movement of people for better job opportunities takes place at jet speed.

We can therefore conveniently use this model globally as a generalization to fix the CEOs’ salary. It is definitely the deciding factor in any goods producing firm’s sales and policy decisions.
