Risto Fotov (risto.fotov@ugd.edu.mk)

Abstract

In this paper IS-LM model, has been introduced as time series model. Standard VAR, VECM test have been applied. Three variables that we estimated were: logarithm of real GDP (q), 3 month interbank interest rate (i), real monetary base (m). VECM mechanism shows that if the system is in disequilibrium alteration in the change of interbank interchange interest rate, log of real US gdp, and monetary base will be downward 5.5%, 4.6%, and 0.4% respectively.

Keywords: IS-LM, VAR, VECM, JMULTI
Literature review of IS-LM Model

The IS-LM model is macroeconomic model that represents the Keynes’s theory. The main idea of the IS-LM model is to show what determined aggregate output in the short run when the prices are fixed. The goal of this model is to analyze the fluctuation of output in the short run through identification of variables that shift aggregate demand. The model gives good base for policymaker in creation adequate macroeconomic policy in short run.

This model is contains form two curves: IS and LM curve. IS curve represents the “investment” and “saving”, and the IS curve shows what is going on in the market for goods and services. LM curve represents “liquidity” and “money”, and the LM curve shows what is happening to the supply and demand for money.¹

Interest rate, Investment and the IS Curve

The Keynesian cross is the main path to IS-LM model. The Keynesian cross is useful because it shows how the spending plans of households, firms, and the government determine the output. From macroeconomics, we already know that there is strong relationship between the interest rate and planned investment. The economists explain this causality relationship between interest rate and planned investment in the following way: interest rate is the cost of borrowing to finance investment project, therefore, an increase in the interest rate reduces planned investment. As a result the investment function slopes downward. On the other side, the investment is one of the components of aggregate output², and thus, the reduction in planned investment shifts the planned-expenditure function downward. The shift in the planned expenditure function causes the level of output to fall form. As we can see from the final panel of following figure, the IS curve summarize the relationship between the interest rate and the level of output.

²Y=C+I+G, when we assume for close economy.
Income, Money Demand and the LM Curve

The theory of liquidity preference shows how the interest rate is determined in the short run. This theory represents how the interest rate adjusts to balance the supply and demand for the most liquid asset in economy – money. To explain the theory of liquidity preference, we start with following equation:
\[(M/P)^t = \bar{M}/\bar{P}^{34}\]  

From this equation we can conclude that this theory assumes that supply of real money balances is fixed. This assumption means that the supply of money does not depend of interest rate. The money supply is chosen by a Central bank as exogenous variable. On the other side, the interest rate is important determinant of how much people choose to hold. The reason is that the interest rate is the opportunity cost of holding money. This means, when the interest rate rises, people want to hold less of their wealth in the form of money. Now, we can write the demand for real money balances:

\[(M/P)^d = L(r,Y)\]  

On the other side, the second important factor which determines the demand for money is the level of output. When output is high, expenditure is high, so people engage in more transactions that require the use of money. Thus, greater level of output implies greater money demand. From previous equation, we can conclude that, the quantity of real money balances demanded is negatively related to the interest rate and positively related to output.

Using the theory of liquidity, we can figure out what happens to the equilibrium interest rate when the level of output changes. From first graph in following figure, we can see that an increase in income shifts the money demand curve to the right. The assumption that the supply of real money balances is unchanged, the interest rate must rise from \(r\) to \(r\) to equilibrate the money market. Therefore, according to the theory of liquidity preference, the higher output leads to higher interest rate. The LM curve plots this relationship between the level of output and the interest rate. The higher the level of output, the higher the demand for real money balances, and the higher the equilibrium interest rate. For this reason, the LM curve slopes upward in the second graph of the figure.  

---

3 The money supply \(M\) is an exogenous policy variable chosen by a central bank.
4 From Keynes's theory, we know that in short run the price level is fixed.
5 Ibid.
The IS-LM model contains two equations that represent the short-run equilibrium in a close economy:

\[
IS \quad Y = C(Y - T) + I(r) + G \quad (3)
\]

\[
LM \quad \frac{M}{P} = L(r,Y) \quad (4)
\]

From the first equation, we can conclude that the main determinant of output is the interest rate. The fact that the model takes all variables as a given except interest rate, the IS curve provides the combination of \( r \) and \( Y \) that satisfy the equation representing the goods market. On the other side, the second equation shows the interest rate as a main variable of market for real money balances, and the LM curve provides the combination of \( r \) and \( Y \) that satisfy the equation representing the money market.
The interaction of the IS and LM curves represents the equilibrium in the market for goods and services and in the market for real money balances for given values of government spending, taxes, the money supply, and the price level. The equilibrium of the economy is the point at which the IS curve and the LM curve cross. This point gives the interest rate $r$ and the level of income $Y$ that satisfy conditions for equilibrium in both the goods market and the money market. In this regard, we can conclude that when economy function of equilibrium level, actual expenditure equals planned expenditure and the demand for real money balances equals the supply.
Data description

These are U.S. time series data they contain: logarithm of real GDP (q), 3 month interbank interest rate (i), real monetary base (m). Original time series are from the Federal Reserve Economic Data (FRED) database. The data included in this file are obtained by the following transformations:

1. Observations for the interest rate and the monetary base are converted to quarterly frequency by averaging the monthly values.
2. \( q = \log(\text{"Real Gross Domestic Product"}) \)
   \( i = \text{"3-Month Bankers' Acceptance Rate"} \)
   \( m = \log(\text{"St. Louis Adjusted Monetary Base"}/\text{"GDP Implicit Price Deflator"}) \)

For a viewer's good, we will plot this data on the following graph:

Te data are quarterly US data from the time period from 1970Q1 to 1997Q4. From the above plot we can roughly see that equilibrium, between money market and goods market is achieved in 1985-1986.
Descriptive statistics of the model

**Sample range:** [1970 Q1, 1997 Q4], \( T = 112 \)

</tbody>
</table>

Normality is not a problem in this model, but heteroscedasticity is present. This is because series have unequal variances. Interest rates are volatile, same as monetary base.
Plot of the series

On the next plot series are being plotted individually.

ADF test

We Augment: $\Delta Y_t = \beta Y_{t-1} + u_t$

1. Constant or “drift” term ($\alpha_0$)
   - random walk with drift
2. Time trend ($T$)
   - test $H_0$: unit root
     - conditional on a deterministic time trend
     - and against $H_A$: deterministic time trend
3. Lagged values of the dependent variable
   - sufficient for residuals free of autocorrelation

$\Rightarrow$ ADF: $\Delta Y_t = \alpha_0 + \gamma T + \beta Y_{t-1} + \delta_1 \Delta Y_{t-1} + \delta_2 \Delta Y_{t-2} + \ldots + \delta_n \Delta Y_{t-n} + u_t$
Problems with unit root tests are as follows:

1. Low power in short time series
   – tend to under-reject $H_0$: unit root against $H_A$: stationarity
   – Endemic problem

2. Critical values for UR tests depend on what the test is conditioned on
   • Critical values differ with specification of the testing equation
     – Inclusion/exclusion of
       • drift term
       • deterministic time trend
       • lags of the differenced variable
         – and the number of lags
   • Another problem
     – terms to control for structural breaks ⇒ also change the critical values

Here is a sample of time series modeling but with time break

\[
y_t = \hat{\mu} + \hat{\theta}DU_t + \hat{\beta}_t + \hat{\gamma}DT_t + \hat{\alpha}D(TB)_t \\
+ \hat{\alpha}y_{t-1} + \sum_{i=1}^{k} \hat{c}_i \Delta y_{t-i} + \hat{\epsilon}_t
\]

• Same as in any ADF test
  $\mu_t$: constant or estimated “drift” term
  $\beta_t$: (deterministic) time trend
  $y_{t-1}$: 1st lag
  $\Delta y_{t-i}$: lagged differences
  • To implement empirically
    – subtract $y_{t-1}$ from both sides
  ⇒ $\beta_1 = ([\alpha\text{-hat}] - 1)$

We use JMULTI software that adds seasonal dummy variables in the models and adds Trend break dummies.
Definition: $T_B$ Time of the break is a period in which a one-time break in structure occurs i.e., a change in the parameters of the trend function. How to identify $T_B$? (Perron, 1990, p.161) Usually “visual inspection is sufficient”, Relate $T_B$ to “major” events (Great Stock or Oil crash)

Terms added to the ADF test

$D(TB)$: Models a one-time change in the intercept, i.e., in the level of the series a “crash” $= 1$ if $t = T_B + 1$; otherwise 0, DV=1 for the single period immediately after the break.

From the above tables about the monetary base, this variable is unit root with a drift variable. Coefficient on the trend variable is small 0.0001 but significant above 1.96 t-stats. From the optimal endogenous lags info criteria optimal number of lags for this variable I three.
This variable interest rates in US economy has unit root and optimal number of endogenous lags by the info criteria is up to 5 lags.

This variable has unit root with a drift term since the coefficient on the trend term is significant, and optimal number of lags are maximum up to 2.

OLS and Nadaraya-Watson regression

Next we present Nadaraya-Watson plots of OLS regressions

First we regress \( q \) on \( i \) (log of real US GDP with three months interest rates)

\[
\text{OLS ESTIMATION} \\
\text{sample range}: \ [1970 \text{ Q1}, 1997 \text{ Q4}], \ T = 112 \\
\text{dependent}: \ q \\
\text{independent}: \ i \\
q = 8.6576 + -1.4159 *i \\
t-values = \{ 174.0741 -2.2817 \} \\
sigma = 0.1962 \ \\
R-squared = 0.0452
\]
From Nadaraya-Watson OLS regression we can see that there is a negative slope between $q$ and $i$, trend is also negative. This means that interest rates and GDP are inversely related.

OLS ESTIMATION

sample range: [1970 Q1, 1997 Q4], $T = 112$

dependent: $q$

independent: $m$

$q = 7.7525 + 0.7996 * m$

t-values $= \{ 242.2745 \, 25.6475 \}$

sigma $= 0.0760$

R-squared $= 0.8567$

$q$ and $m$ are positively related. This means that log of Real GDP and "St. Louis Adjusted Monetary Base"/"GDP Implicit Price Deflator" are positively associated.
Testing for cointegration

\[ \Pi = \text{the equilibrium matrix in the error-correction model.} \]

Procedure is as follows: calculate the rank of \( \Pi \), i.e., number of independent rows or columns there exist 3 possibilities

1. \( \text{Rank}(\Pi) = 0 \)
   - VECM reduces to a VAR in 1\text{st} differences
   - 1\text{st} differences are I(0) \Rightarrow no cointegration

2. \( \text{Rank}(\Pi) = 2 \) This Occurs only when both variables stationary and what follows no common trend \Rightarrow independent \Rightarrow variables over-differenced and correct model is in levels, not 1\text{st} differences

1. \( \text{Rank}(\Pi) = 1 \) One independent row \Rightarrow determinant of \( \Pi = 0 \)
   
   \( (\text{Product of Diagonal 1}) - (\text{Product of Diagonal 2}) = 0 \)

One cointegrating vector (r), Each term in \( \Pi \) is assumed non-zero and long-run or equilibrium coefficient on Y or Z.

- Procedure is as follows: Decompose \( \Pi \) into 2 \( q \times r \) matrices where \( \alpha \) = matrix of short-run “adjustment” coefficients in the EC Model

\( \beta' \) = each row is one of the r

<table>
<thead>
<tr>
<th>Johansen Trace Test for: m i q</th>

\end{bmatrix}

This VAR model contains data form 1971 Q3 to 1997Q4. CUSUM test below shows that m,q,and i equation do not leave the margins of normal distribution.
CHOW test for VAR

Chow test for VAR shows structural stability of the model and if the model is not stable we should continue testing.

---

CHOW TEST FOR STRUCTURAL BREAK

<table>
<thead>
<tr>
<th>Sample range:</th>
<th>[1971 Q3, 1997 Q4], T = 106</th>
</tr>
</thead>
<tbody>
<tr>
<td>Tested break date:</td>
<td>1978 Q1 (26 observations before break)</td>
</tr>
<tr>
<td>Break point Chow test:</td>
<td>555.1126</td>
</tr>
<tr>

</tr>
</tbody>
</table>

From the above table for Chow test, break point chow test showed that the model is not stable, also sample split test showed that, while chow forecast test is only significant at 10%, this means we have to continue with VECM model.
VECM model

VECM model can be introduced in matrix connotation also

\[
\begin{align*}
\Delta Y_t &= -(1 - \Pi_{11}) \Delta Y_{t-1} + \Pi_{12} \Delta Z_{t-1} \\
&\quad - (1 - \Pi_{11} - \Pi_{13}) Y_{t-2} + (\Pi_{12} + \Pi_{14}) Z_{t-2} + \mu_1 + \epsilon_{1t} \\
\Delta Z_t &= \Pi_2 \Delta Y_{t-1} - (1 - \Pi_{22}) \Delta Z_{t-1} \\
&\quad + (\Pi_{21} + \Pi_{23}) Y_{t-2} - (1 - \Pi_{22} - \Pi_{24}) Z_{t-2} + \mu_2 + \epsilon_{2t}
\end{align*}
\]

In matrices

\[
\begin{bmatrix}
\Delta Y_1 \\
\Delta Z_1
\end{bmatrix} =
\begin{bmatrix}
-(1 - \Pi_{11}) & \Pi_{12} \\
\Pi_{21} & -(1 - \Pi_{22})
\end{bmatrix}
\begin{bmatrix}
\Delta Y_{t-1} \\
\Delta Z_{t-1}
\end{bmatrix}
\equiv \Gamma
\]

\[
+\begin{bmatrix}
-(1 - \Pi_{11} - \Pi_{13}) & (\Pi_{12} + \Pi_{14}) \\
(\Pi_{21} + \Pi_{23}) & -(1 - \Pi_{22} - \Pi_{24})
\end{bmatrix}
\begin{bmatrix}
Y_{t-2} \\
Z_{t-2}
\end{bmatrix}
\equiv \Pi
\]

\[
\begin{bmatrix}
\mu_1 \\
\mu_2
\end{bmatrix} +
\begin{bmatrix}
\epsilon_{1t} \\
\epsilon_{2t}
\end{bmatrix}
\]

\[
\begin{bmatrix}
dm(t) \\
dq(t) \\
di(t)
\end{bmatrix} =
\begin{bmatrix}
-0.055 \\
-0.046 \\
-0.004
\end{bmatrix}
\begin{bmatrix}
m(t-1) \\
q(t-1) \\
i(t-1)
\end{bmatrix}
\]

\[
+\begin{bmatrix}
-8.063 & -0.027 & -0.029 & -0.020 & -0.012
\end{bmatrix}
\begin{bmatrix}
CONST \\
S1(t) \\
S2(t) \\
S3(t) \\
TREND(t)
\end{bmatrix}
\]

From the above VECM model, i.e from its VECM mechanism we can see that if the system is in disequilibrium alteration in the change of interbank interchange interest rate, log of real US gdp, and monetary base will be downward 5.5%, 4.6% and 0.4% respectively.
Chow test for VECM

These results below show that CHOW test implies stability here which means that VECM models is stable.

<table>
