Longevity, Life-cycle Behavior and Pension Reform

Peter Haan*, Victoria Prowse†

June 6, 2012

Abstract

How can public pension systems be reformed to ensure fiscal stability in the face of increasing life expectancy? To address this pressing open question in public finance, we use micro data to estimate a structural life-cycle model of individuals' employment, retirement and consumption decisions. Our modeling approach allows life expectancy and the nature of the public pension system to influence the decisions of forward-looking individuals planning for retirement. We calculate that, in the case of Germany, an increase of 4.34 years in the full pensionable age or a cut of 37.7% in the per-year value of public pension benefits would offset the fiscal consequences of the 6.4 year increase in age 65 life expectancy anticipated to occur over the next 40 years. Of these two approaches to coping with the fiscal impact of improving longevity, increasing the full pensionable age generates the largest responses in labor supply and retirement behavior.

Keywords: Life Expectancy; Public Pension Reform; Retirement; Employment; Life-cycle Models; Consumption; Tax and Transfer System.

1 Introduction

Over the last several decades the longevity of individuals living in the developed world has improved considerably and consistently, and this trend looks set to continue.¹ Such a demographic change poses numerous social and economic challenges. Notably, many public pension systems, which are typically compulsory defined benefit schemes, are being strained by the greater pension demands concurrent higher life expectancy. In response to this problem, an important political debate has arisen concerning how to reform public pension systems to address the fiscal demands created by improving longevity. This debate has focused on identifying effective ways of increasing the age-based eligibility requirements associated with public pension benefits. The policy response thus far has reflected this theme: for example, Germany and the US have recently announced plans to gradually increase the full pensionable age, that is the age from which an individual may claim a non-reduced public pension, from 65 to 67 years.

We use a comprehensive dynamic structural model to understand the relationship between life expectancy, the public pension system and individuals' employment, retirement and consumption decisions over the life-cycle. We use the Method of Simulated Moments to estimate the model's parameters. Drawing on this framework, we are the first to analyze how changes in life expectancy affect optimal individual employment, retirement and consumption through the life-cycle. By looking at how individuals respond to changes in individual and cohort-specific longevity, we break new ground by exploring the desirability of changes in the public pension system designed to cope with the fiscal challenges posed by increasing life expectancy. This paper therefore makes a novel contribution to the policy debate on how public pension systems can be reformed to deal effectively with the consequences for Government finances of increasing life expectancy.

Our structural life-cycle model includes stochastic job offers, involuntary separations, saving opportunities and borrowing constraints, early retirement possibilities, unobserved heterogeneity in preferences, employment opportunities and wages, and detailed specifications of the tax and transfer systems. Moreover, the modeling approach naturally allows life expectancy and the public pension system to influence the decisions of forward-looking individuals planning for retirement. This methodology is ideally suited to quantifying the effect of life expectancy on behavior and to exploring the consequences of reductions in public pension generosity. By considering the interplay between life expectancy and public pension reform when individuals may adjust employment, retirement and consumption behavior, we expand on previous applications of structural life-cycle models. In particular, our paper builds on several previous structural studies which have used life-cycle models to investigate the effects of public pension systems on labor supply, retirement and consumption decisions (e.g., Casanova, 2010, French, 2005, French and Jones, 2011, Gustman and Steinmeier, 1986, Gustman and Steinmeier, 2005, Heyma, 2004, Jiménez-Martín and Sanchez Martín, 2007, Rust and Phelan, 1997, and van der Klaauw and Wolpin, 2008) and on work that developed structural life-cycle models in which individuals choose jointly consumption and labor supply (e.g., Imai and Keane, 2004, and Keane

¹E.g., Oeppen and Vaupel (2002) show that over the last 150 years life expectancy at birth in the developed world has been increasing at a rate of 2.5 years per decade, and argue that this linear trend is likely to continue.

and Wolpin, 2001).² Our paper is also related to a small literature that looks at the effect of life expectancy on the saving decision alone (see Brown, 2001, De Nardi et al., 2010, Gan et al., 2004, and Hurd, 1989).

We implement our model in the context of Germany, a country with a compulsory pay-as-you-go defined benefit public pension system which displays many similarities to Social Security in the United States. Couching the analysis in the context of Germany allows us to exploit a unique pattern of variation in the evolution of demographic group-specific life expectancy which arose due to events that followed German reunification in 1990. Specifically, drawing on variation between demographic groups in the extent of improvements in life expectancy, we demonstrate that the estimated model predicts the observed relationship between life expectancy and retirement. This suggests that our model provides a sound basis for counterfactual policy simulations which explore the effect of life expectancy on employment, retirement and consumption behavior.

In terms of data sources, we obtain projections of age-specific life expectancies by cohort, region and gender from the Human Mortality Database for Germany. Data on life expectancy are combined with a sample of older individuals taken from the German Socio-Economic Panel and covering the years 1991 - 2007. In addition to replicating the observed relationship between life expectancy and retirement behavior as discussed above, the fitted model is able to reproduce the distribution of observed wages, the age profile of wealth and the age-specific rates of transitions between employment and unemployment.

The leading results of counterfactual simulations based on the estimated structural life-cycle model are twofold. First, in response to an increase in life expectancy we find that individuals work more and postpone retirement, and thereby increase public pension benefits for their now longer retirement periods. Reflecting this behavioral adjustment, an increase in life expectancy leads to higher net Government revenues received from individuals aged below the full pensionable age; however, the increase in net revenue from individuals aged below the full pensionable age is dwarfed by the increase in public pension demands. Qualitatively, the 6.4 year increase in age 65 life expectancy anticipated to occur over the next 40 years leads average net Government revenue per person, summed over the life-cycle starting at age 40 years and continuing until death, to decrease by approximately 75000 Euros.

Second, we demonstrate striking differences between behavioral responses to two revenue equivalent reductions in public pension generosity. We calculate that the fiscal consequences of the 6.4 year increase in age 65 life expectancy anticipated to occur over the next 40 years can be offset by either an increase of 4.34 years in the full pensionable age or a cut of 37.7% in the per-year value of public pension benefits. We find that the increase in the full pensionable age elicits a marked increase in the employment rate, while a revenue equivalent the cut in the per-year value of public pension benefits has little impact on employment outcomes. Intuitively, the increase in the employment rate associated with the increase in the full pensionable age arises because the age-based eligibility rules embedded in the public pension system represent binding constraints on access to public pension benefits for many individuals. Meanwhile, those

²A largely separate literature presents empirical evidence from micro data of a direct effect of pension rights on retirement decisions (e.g., Blau, 1994, Blundell et al., 2002, Disney and Smith, 2002, French and Jones, forthcoming, Friedberg, 2000, and Friedberg and Webb, 2005). Blöndal and Scarpetta (1997) and Gruber and Wise (1998) demonstrate a similar relationship at the macro level. Gruber and Wise (2004) and Gruber and Wise (2007) survey the micro and macro evidence.

individuals most affected by a cut in the per-year value of public pension benefits are likely to be in employment and ineligible for early retirement, and hence are generally unable to increase employment. We compute that expected total per-person post age 40 years consumption is over 100000 Euros higher if the fiscal consequences for the Government of 40 years worth of improvements in longevity are counteracted by an increase in the full pensionable age rather than a revenue equivalent cut in the per-year value of pension benefits.

This paper proceeds as follows. Section 2 outlines our life-cycle model. Section 3 describes our data sources. Section 4 provides an overview the estimation methodology, presents our structural parameter estimates and demonstrates the model’s goodness of fit. Section 5 discusses the results of counterfactual policy simulations. Finally, Section 6 concludes.

2 Model

2.1 Overview

To examine the impact of life expectancy on life-cycle behavior and to explore the effectiveness of public pension reforms, we develop a rich dynamic structural model of individual’s employment, retirement and consumption decisions over the life-cycle. We propose a discrete-time finite-horizon model. Each quarter, i.e., every three months, an individual chooses his or her current labor market state and current consumption.³ We distinguish three labor market states: full-time work (f); unemployment (u); and retirement (r).⁴ Retirement is an absorbing state. Individuals are indexed by $i = 1, \dots, N$, and age, measured in quarters of a year, is indexed by t .⁵ The maximum possible age to which an individual can live is denoted by \bar{T} . We follow the life tables and use $\bar{T} = 110$ years. We focus on the employment, retirement and consumption behavior of individuals aged 40-65 years. Following De Nardi et al. (2010), in the interest of ensuring that our empirical analysis captures precisely the relevant institutional and environmental factors we study only those individuals who reside in single-adult households and who do not have dependent children.⁶

Each period, an individual enjoys a flow of utility which depends on current consumption, $c_{i,t}$, current leisure and individual-specific preference shifters. We use $U_{i,t}(c_{i,t}, j)$ for $j = f, u, r$ to denote individual i ’s age t flow utility from state j . Following Low et al. (2010), we adopt

³Quarterly decision making allows accurate modeling of the Unemployment Insurance system.

⁴Full-time work is 39 hours of work per week. This is the median hours of work of sampled individuals.

⁵To improve readability we do not introduce further subscripts to index specific cohorts or years: cohort information is specific to the individual, and together with age information, the year is thereby defined.

⁶Older non-retired individuals constitute the demographic group for which we expect that behavior is most sensitive to life expectancy and the design of the pension system. Indeed, previous work has shown that the labor supply and retirement decisions of older, yet working age, individuals are relatively elastic with respect to income (e.g., Gruber and Wise, 2004, Haveman et al., 1991, and Lalive et al., 2006). Hence, there should be little loss restricting the analysis to older individuals. Single-adult households constitutes around 30% of all households in which the household head is aged 40-65 years. The public pension system is administered at the individual level and therefore our results for singles are indicative of the behavior of other demographic groups.

the following constant relative risk aversion (CRRA) specification for preferences:

$$U_{i,t}(c_{i,t}, f) = \beta \frac{(c_{i,t}(1 - \eta_i))^{1-\rho}}{1 - \rho} + \varepsilon_{i,f,t}, \quad (1)$$

$$U_{i,t}(c_{i,t}, j) = \beta \frac{c_{i,t}^{1-\rho}}{1 - \rho} + \varepsilon_{i,j,t} \text{ for } j = u, r. \quad (2)$$

In equations (1) and (2), ρ is the coefficient of relative risk aversion, and η_i describes the complementarity between consumption and leisure. We impose $\eta_i \in [0, 1)$, and this has two implications. First, we can interpret η_i as the share of consumption necessary to compensate individual i for the disutility of working. Second, consumption and leisure are Frisch complements, meaning that, *ceteris paribus*, the marginal utility of consumption is higher for working individuals than for either unemployed individuals or retired individuals. We allow unobserved heterogeneity in the complementarity between leisure and consumption by assuming that $\eta_i | \chi_i \sim N(\mu_\eta, \sigma_\eta^2)$, where χ_i denotes the individual's observed characteristics at the time of labor market entry.⁷ The unobservables $\varepsilon_{i,f,t}$, $\varepsilon_{i,u,t}$ and $\varepsilon_{i,r,t}$ represent transient individual-specific preference shifters while the parameter β determines the importance of consumption and leisure in preferences, relative to the transient individual-specific unobservables.^{8,9}

Current consumption is the sum of current net income and current dissaving. Current net income depends on the individual's gross incomes from employment and from interest on wealth, and on the contemporaneous tax, transfer and pension systems. Our model includes an accurate representation of the tax system, including income tax deductions and Social Security Contributions. The model also includes the two leading forms of out-of-work transfers: Social Assistance; and Unemployment Insurance. Appendix E provides further information about the tax and transfer systems. Further details about the modeling of the pension system can be found in Section 2.4.¹⁰

⁷To guarantee that $\eta_i \in [0, 1)$ we truncate η_i from above at 0.999 and from below at zero. According to this specification, preference heterogeneity occurs independently of observed individual characteristics at the time of labor market entry. However, due to the endogenous accumulation of experience and wealth occurring within the model, preference heterogeneity will be correlated with observed individual characteristics at dates subsequent to labor market entry. We will estimate the model directly and therefore our empirical analysis accounts fully for such processes.

⁸The ε s are assumed to occur independently over individuals. The ε s for individual i are assumed to occur independently over time and over the labor market states $j = f, u, r$. Further, the individual's age t ε s are assumed to be independent of the individual's age t observed characteristics. Additionally, $\varepsilon_{i,j,t}$ for all i, j and t is assumed to have a type I extreme value distribution. The inclusion of this form of unobservables in the flow utilities has the effect of smoothing the value function and thus facilitates estimation of the structural parameters.

⁹The utility function described by equations (1) and (2) is a minor generalization of a Cobb-Douglas utility function: Equations (1) and (2) can be rewritten as

$$U_{i,t}(c_{i,t}, j) = c_{i,t}^{1-\rho} L_{i,j}^\rho + \varepsilon_{i,j,t} \text{ for } j = f, u, r, \quad (3)$$

where $\varepsilon_{i,j,t} = \beta^{-1}(1 - \rho)\varepsilon_{i,j,t}$ and $L_{i,j} = (1 - \eta_i H_j)^{(1-\rho)/\rho}$ where H_j represents the percentage of full-time working hours spent in employment in state j (for the labor market states appearing in our model we have $H_u = H_r = 0$ and $H_f = 1$).

¹⁰The German tax, transfer and pension systems were subject to several reforms during the sample period. We model current net income as a function of the contemporaneous tax, transfer and pension systems. We assume that individuals expect that the current tax and transfer systems will persist into future years (see Keane, 2011, for further discussion of this assumption). This assumption is plausible because the reforms of the tax and transfer systems that occurred during the sample period either were announced at short notice or had highly uncertain implementation schedules. We also assume that individuals expect that the cohort-specific rules defining the public pension system will be maintained indefinitely. In Appendix F.4 we argue that this assumption is realistic.

Individuals are forward-looking and each period make employment, retirement and consumption decisions to maximize the discounted expected value of future utility. An individual's optimization problem age t is given by

$$\max_{d,c} E_t \sum_{s=t}^{\bar{T}} \delta^{s-t} k_{i,s,t} U_{i,s}(c_{i,s}, d_{i,s}). \quad (4)$$

In the above $d_{i,t} \in \{f, u, r\}$ is a categorical variable which codes the individual's age t labor supply and retirement behavior. The variable d details the individual's employment and retirement behavior in each remaining period of the individual's life. Similarly, c is a vector that describes the individual's consumption choice in each remaining period of the individual's life. The operator E_t is an expectation conditional on the individual's age t information set. Payoffs occurring in the future are discounted due to subjective time discounting and mortality risk; $\delta \in [0, 1]$ is the subjective time discount factor, and $k_{i,s,t}$ is the probability of the individual surviving until age s conditional on being aged t .

The inclusion of survival probabilities in the individual's objective function reflects the dependence of life-cycle utility on life expectancy. We follow, *inter alios*, De Nardi et al. (2010), van der Klaauw and Wolpin (2008) and Rust and Phelan (1997) and allow individual-level heterogeneity in life expectancy. Specifically, we allow variation in survival rates, and therefore life expectancy, according to gender and region of residence. Additionally, extending on previous studies, we allow life expectancy to be cohort-specific and therefore we capture the sizable improvements in life expectancy that have occurred in recent years. In Section 3.2 we discuss the empirical relevance and statistical advantages associated with our relatively rich approach to modeling life expectancy.

The optimization process is subject to an intertemporal budget constraint. In addition, behavior is subject to constraints on borrowing and on the availability of employment and retirement opportunities. We describe below: (i) the processes that determine job offers and involuntary separations and thereby dictate employment opportunities; (ii) the composition of gross wage income; (iii) public pension benefits and early retirement opportunities; (iv) borrowing constraints, consumption possibilities and the intertemporal budget constraint; and (v) the optimal arrangement of employment, retirement and consumption over the life-cycle.

2.2 Employment Opportunities

An individual's behavior is constrained by the availability of employment opportunities (see Blundell et al., 1987, and Blundell et al., 1998, for discussion of labor supply rationing). Rationing of labor supply is an important life-cycle phenomena: it contributes to prolonged periods of unemployment and therefore affects retirement incentives when public pension benefits are linked to life-time labor market outcomes.

Employment opportunities are modeled as follows. Each period an unemployed individual receives a job offer with probability $\Theta_{i,t}$. Upon receipt of a job offer, the individual observes the current gross wage, $w_{i,t}$, associated with the job opportunity. The age t job offer probability takes the form

$$\Theta_{i,t} = \Phi(\lambda_{\Theta} x_{i,t} + \mu_i^{\Theta}). \quad (5)$$

Here and henceforth $\Phi(\cdot)$ denotes the cumulative distribution function of a standard normal random variable. We allow the job offer probability to depend on age, region of residence and health status, and variables measuring these characteristics are included in $x_{i,t}$. λ_Θ is a suitably dimensioned parameter vector. Finally, μ_i^Θ represents unobserved individual characteristics. An individual in receipt of a job offer has the option of moving into employment in the current period. With probability $(1 - \Theta_{i,t})$ a previously unemployed individual does not receive a job offer at age t , in which case a transition into employment in the current period is impossible.

Similarly, each period an employed individual experiences an involuntary separation with probability $\Gamma_{i,t}$. The age t probability of an involuntary separation takes the form

$$\Gamma_{i,t} = \Phi(\lambda_\Gamma x_{i,t} + \mu_i^\Gamma), \quad (6)$$

where λ_Γ is a suitably dimensioned parameter vector and μ_i^Γ is an unobserved individual effect. An individual subject to an involuntary separation does not have the option of remaining in employment in the current period. With probability $(1 - \Gamma_{i,t})$ a previously employed individual does not experience an involuntary separation and has the opportunity to stay in employment and to be paid new gross wage, $w_{i,t}$.

We interpret the unobserved individual effects that appear in the job offer and involuntary separation probabilities as permanent unobserved individual characteristics that impact on an individual's ability to find or keep a job. These unobservables are assumed to be assigned to an individual at the time of first labor market entry. The joint distribution of the unobserved individual effects is given by $[\mu_i^\Theta, \mu_i^\Gamma] | \chi_i \sim N(0, \Sigma^\mu)$.

2.3 Gross Wage Offers

Gross wage income is an important component of current and future financial incentives. Therefore, we adopt the following rich specification for offered gross hourly wages

$$\log(w_{i,t}) = \lambda z_{i,t} + \alpha_i + \tau_{i,t} + v_{i,t}. \quad (7)$$

In the above, $z_{i,t}$ contains observed individual characteristics including education, region of residence and experience, and λ is a suitably dimensioned parameter vector. The inclusion of experience is important here because it captures the endogenous accumulation of experience-based human capital (e.g., Eckstein and Wolpin, 1989, and Keane and Wolpin, 1997).

The final three terms in the wage equation are the unobserved components of wages. α_i is a permanent individual-specific random effect, representing ability or skill. We take α_i to be assigned to an individual at the time of first labor market entry and assume $\alpha_i | \chi_i \sim N(0, \sigma_\alpha^2)$. $\tau_{i,t}$ is a persistent unobservable, which we interpret as an employer-employee match-specific productivity effect. For an individual who was employed in the previous period, $\tau_{i,t}$ keeps the same value as in the previous period with probability Π , and with probability $(1 - \Pi)$ the individual's match-specific productivity is subject to a shock. In the latter case, the individual receives a new match-specific productive effect $\tau_{i,t} | \varphi_{i,t} \sim N(0, \sigma_\tau^2)$, where $\varphi_{i,t}$ denotes the individual's age t characteristics, including previous labor market outcomes and previous unobserved characteristics. An individual who was unemployed in the previous period and who is in receipt of a job

offer in the current period receives a new match-specific productivity shock $\tau_{i,t}|\varphi_{i,t} \sim N(0, \sigma_\tau^2)$. In contrast to Low et al. (2010), we do not model or observe transitions between employers; we identify Π and σ_τ^2 from the persistence in individual-specific wage observations (see Table 6). Finally, $v_{i,t}|\varphi_{i,t} \sim N(0, \sigma_v^2)$ is a transitory wage shock. The parameters of the wage process are estimated jointly with the other structural parameters (see Section 4.1).¹¹

2.4 Public Pension Benefits and Early Retirement Opportunities

Similar to many public pension systems, German public pension benefits reflect an individual’s employment and earnings outcomes prior to retirement, and this linkage works to strengthen the interplay between life expectancy, the public pension system and life-cycle behavior. We provide here an overview of the relevant aspects of the German public pension system. Unless noted otherwise, the model is estimated with the specification of pension benefits described below. Further details can be found in Appendix F.¹²

Public pension benefits in Germany are linked to an individual’s labor market history via a quantity we refer to as “weighted pension points”. An individual accumulates one pension point for every year of employment and such pension points attract a weight of $\min\{w_{i,t}/\bar{w}_{i,t}, Max_{i,t}\}$, where $\bar{w}_{i,t}$ denotes the mean gross wage in the period when individual i is age t and $Max_{i,t}$ denotes the year-specific cap on pension point weights. During the sample period, the cap on pension point weights was roughly equal to two in all years. An individual also accumulates one pension point for every year of Unemployment Insurance-eligible unemployment. Such pension points are allocated a weight of $\min\{0.8 \times w_{i,t'}/\bar{w}_{i,t}, 0.8 \times Max_{i,t}\}$, where t' denotes the age at which the individual was last employed. Thus, up to a cap of roughly 1.6, an unemployed individual’s pension points are weighed by the ratio of 80% of the individual’s most recent gross wage relative to the current mean gross wage.

Age-based criteria govern access to public pension benefits and the generosity of public pension benefits. Arguably the most important age-based parameter is the full pensionable age. At this age, which is 65 years for the individuals under study, an individual can retire and receive a publicly provided pension with a value proportional to the sum of weighted pension points accumulated prior to retirement. The German public pension system is relatively generous: according to Börsch-Supan and Schnabel (1998), in 1998 public pension benefits provided a replacement rate of around 70% of pre-retirement net earnings for an individual retiring at the full pensionable age with 45 years of working experience and average life-time earnings.

The public pension system offers numerous opportunities for retirement prior to the full pensionable age and our model captures most important routes into early retirement. Specifically, our model recognizes that an individual may be eligible for retirement prior to the full pensionable age on the grounds of: (i) gender, specifically being a woman; (ii) disability; or (iii) working history, specifically having previously worked at least 35 years. Eligibility for early

¹¹At all ages the three unobserved components of wages are assumed to be mutually independent and independent of the unobservables $[\mu_i^\ominus, \mu_i^\Gamma]$ that affect the job offer and involuntary separation probabilities.

¹²Börsch-Supan and Wilke (2004) note that the public pension system in Germany accounts for approximately 85% of pension income, while individual and occupational pensions account for 10% and 5% of pension income respectively. We refrain from modeling individual and occupational pensions. Instead, we assume that the provision for private saving afforded by our model approximates the saving opportunities offered by individual and occupational pensions.

retirement on the grounds of gender or working history is dependant on the individual's age (e.g., only those who have worked at least 35 years may retire from age 63 years). The age, gender and working history-based eligibility criteria for early retirement are entirely objective and the relevant rules are hard-coded into the model. When doing this, we account fully for intertemporal variation in the early retirement eligibility criteria. In contrast, the rules that determine eligibility for public pension benefits on the grounds of disability are complex and the operationalization of these rules has inevitably been somewhat subjective. For the purpose of implementing our model, we assume that individual i has a probability $\Upsilon_{i,t}$ of being eligible, due to disability, for early retirement. The age t probability of being eligible for public pension benefits on the grounds of disability is as follows

$$\Upsilon_{i,t} = \Phi(\lambda_{\Upsilon} q_{i,t}), \quad (8)$$

where $q_{i,t}$ contains variables that measure the individual's gender and health status, and λ_{Υ} is a suitably dimensioned parameter vector. The per-year value of public pension for an individual taking early retirement depends on the year-specific legislation, gender, disability status, working history and age. Appendix F.3 provides further details.

2.5 Borrowing, Consumption and the Intertemporal Budget Constraint

Individuals may save and borrow. Wealth ($W_{i,t}$) here refers to an individual's private wealth holdings, and therefore excludes the value of any entitlements to the public pension or other social programs. The individual faces borrowing constraints which restrict wealth to be non-negative, that is $W_{i,t} \geq 0$. This assumption, which follows French (2005) and Low et al. (2010), reflects that borrowing typically requires collateral and that individuals are unable to borrow against future earnings or future Unemployment Insurance, Social Assistance or public pension benefits.

Subject to the above-described borrowing constraint, each period, a non-retired individual chooses a consumption level, $c_{i,t}$. Quarter-by-quarter wealth accumulation for a non-retired individual is described by the following intertemporal budget constraint

$$W_{i,t+0.25} = W_{i,t} + 1(d_{i,t} = f)m_{i,f,t} + 1(d_{i,t} = u)m_{i,u,t} - c_{i,t}. \quad (9)$$

In the above $m_{i,f,t}$ and $m_{i,u,t}$ are the net incomes that arise from full-time employment and unemployment. (These net incomes are determined by the tax and transfer systems, gross wage income and income from wealth - see Appendix E). Note that, given consumption behavior, wealth accumulation depends on the real interest as the net incomes $m_{i,f,t}$ and $m_{i,u,t}$ include the net-of-tax value of interest income. In contrast to the models of retirement behavior developed by, e.g., French and Jones (2011) and Rust and Phelan (1997), we do not include medical expenses. This is reasonable because Germany has a universal health care system.

We assume that a retired individual's consumption is consistent with the actuarially fair annuity value of accumulated wealth. The per-period consumption enjoyed by an individual who retires at age t thus given by

$$c_{i,t}^r = m_{i,r,t} + a_{i,t}, \quad (10)$$

where $a_{i,t}$ denotes per-period annuity value of wealth for an individual who retires at age t . This specification captures the primary intertemporal incentives important for the current application. In particular: (i) wealth accumulation prior to retirement is valuable in retirement; (ii) the value of accumulated wealth is negatively related to life expectancy (as the actuarially fair annuity value of wealth depends negatively on life expectancy); and (iii) financing consumption out of accumulated wealth is a substitute for funding consumption from public pension benefits.

2.6 Optimal Labor Supply, Retirement and Consumption

2.6.1 Solution Method

Drawing on dynamic programming techniques, we use our model to describe an individual's optimal employment, retirement and consumption behavior over the life-cycle. An individual's age t optimization problem can be expressed in terms of the state-specific value functions $V_t^{j,c}(p_{i,t})$ for $j = f, u, r$, which define the maximized discounted expected value of the individual's future life-cycle utility conditional on being in state j with current consumption of c . Here, $p_{i,t}$ denotes the time t values of the state variables for individual i .¹³ Using \check{t} to denote the individual's age in the next quarter, i.e., $\check{t} \equiv t + 0.25$, the state-specific value functions are defined recursively as follows

$$V_t^{f,c}(p_{i,t}) = U_{i,t}(c, f) + \delta k_{i,\check{t},t} E_t \left[\Gamma_{i,\check{t}} \{ \Lambda_{i,\check{t}} \max\{V_{\check{t}}^u(p_{i,\check{t}}), V_{\check{t}}^r(p_{i,\check{t}})\} + (1 - \Lambda_{i,\check{t}}) V_{\check{t}}^u(p_{i,\check{t}}) \} + (1 - \Gamma_{i,\check{t}}) \{ \Lambda_{i,\check{t}} \max\{V_{\check{t}}^f(p_{i,\check{t}}), V_{\check{t}}^u(p_{i,\check{t}}), V_{\check{t}}^r(p_{i,\check{t}})\} + (1 - \Lambda_{i,\check{t}}) \max\{V_{\check{t}}^f(p_{i,\check{t}}), V_{\check{t}}^u(p_{i,\check{t}})\} \} \right], \quad (11)$$

$$V_t^{u,c}(p_{i,t}) = U_{i,t}(c, u) + \delta k_{i,\check{t},t} E_t \left[(1 - \Theta_{i,\check{t}}) \{ \Lambda_{i,\check{t}} \max\{V_{\check{t}}^u(p_{i,\check{t}}), V_{\check{t}}^r(p_{i,\check{t}})\} + (1 - \Lambda_{i,\check{t}}) V_{\check{t}}^u(p_{i,\check{t}}) \} + \Theta_{i,\check{t}} \{ \Lambda_{i,\check{t}} \max\{V_{\check{t}}^f(p_{i,\check{t}}), V_{\check{t}}^u(p_{i,\check{t}}), V_{\check{t}}^r(p_{i,\check{t}})\} + (1 - \Lambda_{i,\check{t}}) \max\{V_{\check{t}}^f(p_{i,\check{t}}), V_{\check{t}}^u(p_{i,\check{t}})\} \} \right], \quad (12)$$

$$V_t^r(p_{i,t}) = U_{i,t}(c_{i,t}^r, r) + \delta k_{i,\check{t},t} E_t V_{\check{t}}^r(p_{i,\check{t}}). \quad (13)$$

In (11)-(13) above, $\Lambda_{i,\check{t}}$ is the individual's probability of being eligible for retirement at age \check{t} .¹⁴ Meanwhile, $V_{i,\check{t}}^f(p_{i,\check{t}})$ and $V_{i,\check{t}}^u(p_{i,\check{t}})$ are defined as the age \check{t} value functions associated with age \check{t} employment and unemployment, respectively, after age \check{t} consumption has been optimized. Specifically,

$$V_{i,\check{t}}^j(p_{i,\check{t}}) = \max_c V_{i,\check{t}}^{j,c}(p_{i,\check{t}}) \quad \text{for } j = f, u. \quad (15)$$

¹³The state variable are: W ; q ; μ^Θ ; μ^Γ ; η ; τ ; v ; ε_j for $j = f, u, r$; α ; z ; x ; and the current values of the parameters that define the tax, transfer and pension systems. See Sections 2.1-2.5 for further details.

¹⁴Following the discussion above in Section 2.4, an individual may be eligible for retirement at age \check{t} either on the grounds of disability, an event which occurs with probability $\Upsilon_{i,\check{t}}$ as defined above in equation (8), or due to having satisfied the relevant age, gender and working history based criteria. Therefore, the probability of an age \check{t} individual being eligible for retirement, $\Lambda_{i,\check{t}}$, takes the following form:

$$\Lambda_{i,\check{t}} = \begin{cases} 1 & \text{if age, gender and working history based criteria for retirement eligibility are satisfied;} \\ \Upsilon_{i,\check{t}} & \text{otherwise.} \end{cases} \quad (14)$$

Finally, all individuals may retire at the full pensionable age of 65 years and therefore we have $\Lambda_{i,65} = 1$.

Subject to the above discussed constraints on the availability of employment opportunities and on wealth accumulation, each period, an individual is able to adjust his or her employment, retirement and consumption behavior. At age t , a forward-looking optimizing individual in possession of a job offer but not eligible for retirement will choose employment and a current-period consumption level of c' if and only if $V_t^{f,c'}(p_{i,t}) > \max_{c,c \neq c'} V_t^{f,c}(p_{i,t})$ and $V_t^{f,c'}(p_{i,t}) > \max_c V_t^{u,c}(p_{i,t})$, and otherwise will choose unemployment and consumption $c = \max_c V_t^{u,c}(p_{i,t})$. If such an individual instead is eligible for retirement then he or she will choose employment and a current-period consumption level of c' if, in addition to the previous two inequalities, it is also the case that $V_t^{f,c'}(p_{i,t}) > V_t^r(p_{i,t})$. An individual who does not have a job offer and is not eligible early retirement will be unemployed with a current-period consumption level of $c = \max_c V_t^{u,c}(p_{i,t})$. Alternatively, if this individual is eligible for retirement then he or she will choose unemployment with a current-period consumption level of c' if and only if $V_t^{u,c'}(p_{i,t}) > \max_{c,c \neq c'} V_t^{u,c}(p_{i,t})$ and $V_t^{u,c'}(p_{i,t}) > V_t^r(p_{i,t})$. Upon reaching the full pensionable age all remaining non-retired individuals must enter retirement.

2.6.2 Discussion

Several mechanisms link an individual's current employment, retirement and consumption decisions with expected future payoffs. We discuss here those intertemporal linkages related directly to retirement and explain the interaction of these intertemporal linkages with life expectancy.

Current employment adds to an individual's stock of pension points and therefore, holding fixed the age of retirement, increases pension income retirement. Current unemployment has a similar albeit smaller effect, provided that the unemployed individual is receiving Unemployment Insurance. Furthermore, working in the current period adds to the individual's experience which, in the presence of positive wage returns to experience, leads to higher expected future wage offers and, *ceteris paribus*, to higher public pension benefits in retirement. Finally, accumulation of wealth prior to retirement, *ceteris paribus*, allows an individual to increase income in retirement.

Life expectancy interacts with the above-described intertemporal dependencies. An increase in life expectancy increases the expected duration over which an individual will receive public pension benefits. An increase in life expectancy therefore, *ceteris paribus*, raises the expected return to accumulation of pension points, and creates an incentive to postpone retirement. Further, an increase in life expectancy increases the time over which an individual may enjoy the returns from accumulated wealth. Therefore, ignoring interactions with other behavioral adjustments, the incentive to save is increasing in life expectancy.

However, the total effect of an increase in life expectancy on behavior over the life-cycle is, *a priori*, impossible to determine. Since savings and entitlements to public pension benefits are substitutes in terms of their effects on utility in retirement, individuals may respond to an increase in life expectancy by increasing employment and reducing wealth accumulation, or vice versa. Moreover, an increase in life expectancy may lead to higher saving or increased employment early in the life-cycle followed by earlier retirement. Optimizing behavior does, however, rule out an increase in life expectancy causing weakly lower saving and weakly higher unemployment early in the life-cycle followed by strictly earlier retirement.

3 Data Sources and Sample Selection

Estimation uses data from the German Socio-Economic Panel and the Human Mortality Database.

3.1 German Socio-Economic Panel (SOEP)

The German Socio-Economic Panel (SOEP) is an annual, representative panel survey of over 11000 German households. As described by Wagner et al. (2007), the SOEP contains information about socio-economic variables, including income and working behavior, at the individual and household levels. We use the SOEP surveys from the years 1992 - 2008, which contain retrospective information covering the fiscal years 1991 - 2007.

Our sample selection criteria are designed to ensure a clean empirical implementation above-described theoretical model. As justified in Section 2.1, we use a sample of individuals aged 40 - 65 years who reside in single adult households and who do not have dependent children.¹⁵ Further, we exclude from our analysis those individuals whose primary earnings are from self-employment as well as those in full-time education because, in both cases, labor supply behavior differs substantially from that of the rest of the population under analysis. Our final sample is an unbalanced panel with 40409 person-quarter observations. The sample contains 2389 distinct individuals of whom 55% are women.

The SOEP data set contains detailed self-reported information about individuals' employment and retirement behavior in each month. We group the monthly information and form quarterly observations with an individual's labor market status in the first month of the quarter determining the quarterly outcome. All individuals who report that they are currently retired, or who have reported being retired at some point in the past, are classified as retired. In addition, any individuals who report being non-retired at age 65 or older are reclassified as retired.¹⁶ The group of unemployed individuals comprises non-working, non-retired individuals. Given this definition, an unemployed individual is either voluntarily or involuntarily unemployed; this construction is in line with the theoretical framework, in which involuntary job separations, voluntary quits and refusals of job offers are permitted.¹⁷ A measure of experience at the time that the individual entered the sample is constructed from retrospective information. This variable is updated at quarterly intervals over the sample period in accordance with the individual's observed employment behavior.

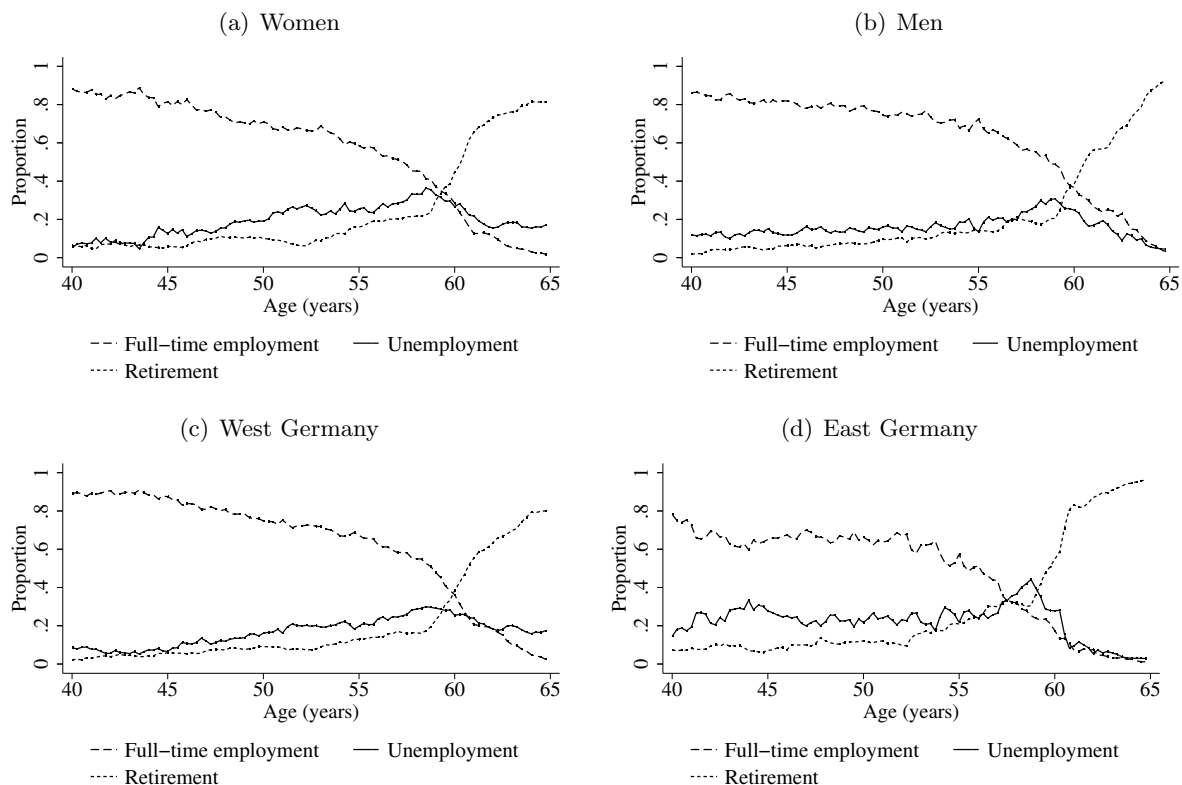

Figure 1 shows the shares of employment, unemployment and retirement by age for men and women and for east and west Germans, averaged over the observation period. We note that early retirement common for individuals in their late 50s and early 60s. Further, there are large differences in employment and retirement behavior according to region of residence: averaged over the whole age distribution, the employment rate is about 10 percentage points higher in west Germany than in the east, and older east Germans have a higher propensity to

¹⁵We assume that family composition does not change in the future. However, our model is fully applicable to individuals who have experienced alternative household compositions, specifically marital status and dependent children, before entering the sample. Appendix C explains how this is achieved.

¹⁶Our definition of retirement corresponds closely to observed behavior: Fewer than 5% of retired individuals are simultaneously in employment and only 1% of retired individuals report that they work full-time. Fewer than 1% of the sampled individuals continue to work beyond age 65 years.

¹⁷Given our sample selection criteria, less than 5% of the male (female) population under study works fewer than 30 (25) hours per week. It is therefore reasonable to treat all employment as full-time work.

Figure 1: Employment, unemployment and retirement over the life-cycle by gender and region of residence

retire than west Germans of the same age. These differences are likely related to the relatively poor economic conditions in east Germany.

The SOEP data set includes individuals' gross earnings in the month prior to the interview date. Using the corresponding working hours, including hours of payed overtime work, we construct a gross hourly wage measure. We follow Fuchs-Schuendeln and Schuendeln (2005) and construct a measure of individual-level wealth based on the yearly financial information available in the SOEP. Specifically, an individual's wealth is defined as the sum of net property equity and non-property wealth, where the latter is computed from capital income assuming a real rate of return of 3% per annum.¹⁸ Wealth and wages are converted to year 2000 prices using the Retail Price Index. The average observed gross hourly wage is 15.65 Euros and average individual wealth is 40037 Euros.

3.2 Human Mortality Database (HMD)

We obtain information about longevity in Germany from the relevant life tables in the Human Mortality Database (HMD).¹⁹ The life tables include survival probabilities and life expectancies that vary by age, birth cohort, region of residence (east or west Germany) and gender and are available for the years 1991 - 2007. Based on the information in the HMD, we assign a

¹⁸A real interest rate of 3% per annum is in line with the rates prevailing in the capital markets: Deutsche Bundesbank (2001) reports an average ex ante real interest rate of 3.13% in Germany for the period 1994-2001 (based on estimated inflation), and this result is supported by the calculations of Garnier et al. (2005).

¹⁹Human Mortality Database is provided by the University of California, Berkeley (USA) and Max Planck Institute for Demographic Research (Germany). The database is available at www.mortality.org.

Figure 2: Life expectancy at age 40 years: evolution over time in east and west Germany

Source: Authors' calculations based on the Human Mortality Database.

demographic group-specific and cohort-specific survival probability and life expectancy to each observation in our SOEP sample.²⁰

Figure 2 shows the evolution over time of life expectancy at age 40 years for east and west German men and women. As expected, we observe longer life expectancies for women and, irrespective of gender or region, an upward trend in life expectancy over time. As well documented in the demographic literature, e.g., Gjonça et al. (2000), life expectancy in east Germany in 1991, immediately after German reunification, was considerably lower than in west Germany: in 1991 a 40 year old east German man expected to live 2.7 years less than his west German counterpart, and the corresponding difference for women was 2.4 years. More important for our purposes are the different time trends by gender and region: between 1991 and 2007, there was a strong east-west convergence in life expectancy for women and moderate east-west convergence for men. Specifically, by 2003 there was hardly any east-west difference in life expectancy for women and by 2007 the east-west life expectancy gap for men had fallen to one year. According to Gjonça et al. (2000), Nolte et al. (2002) and Kibele and Scholz (2008), the leading reason for this convergence was improvements in the medical system in east Germany.

In light of the above documented heterogeneity in life expectancy, in the empirical implementation of our structural life-cycle model we permit variation in life expectancy according to age, birth cohort, gender and region of residence. This maximizes the model's accuracy. Furthermore, by drawing on variation between demographic groups in the extent of improvements in life expectancy over time, we are able to estimate the relationship between life expectancy and retirement decisions, controlling for age, time and cohort effects. This quantity is informative about the extent to which individuals condition behavior on objectively-measured life expectancy. As a powerful in-sample goodness of fit test, we compare the relationship between life expectancy and retirement decisions as implied by our estimation results with the corresponding quantity

²⁰The HMD does not contain information about marital status. In general, the life expectancy of single individuals tends to be lower than that of married individuals. This may lead bias our estimate of the subjective time discount factor downwards. However, we are not concerned about this issue as there is evidence the relationship between life expectancy and marital status is strongest for prime-age individuals and is weak, or even nonexistent, for older individuals (see Johnson et al., 2000). Moreover, it is likely that individuals are less well informed about the relationship between life expectancy and marital status than they are about variation in life expectancy according to gender, region or birth cohort.

observed in our sample.²¹

4 Estimation Strategy and Results

4.1 Estimation, Identification and Treatment of the Initial Conditions

As in Gourinchas and Parker (2002), French (2005) and French and Jones (2011), we estimate the parameters of our model using the Method of Simulated Moments (MSM): parameters are chosen to minimize the distance between a set of moments pertaining to the values of the endogenous variables, namely wages, wealth levels, and employment and retirement outcomes, as observed in our sample and the average values of the same moments in a number of simulated data sets. The construction of each simulated data set starts from the empirical distribution of the exogenous individual characteristics, such as gender, education and region of residence, observed in our sample. Given a trial parameter vector θ_t , we simulate initial values of the endogenous variables by drawing from a reduced form model. We then simulate wage offers and employment, retirement and consumption outcomes in subsequent quarters of the sample period based on the above-described structural model. The value function is approximated using the simulations and interpolation method described in Appendix A.

Suppose that a total of p moments are used in the MSM estimation. Let M^o denote the p -by-1-dimensional vector of moments constructed from our sample observations. Further, let $M_k^s(\theta_t)$ denote the same vector of moments constructed using the k^{th} simulated sample obtained using the parameter vector θ_t . The MSM parameter estimates are the value of θ_t that minimizes the weighted quadratic distance $(\bar{M}^s(\theta_t) - M^o)'W(\bar{M}^s(\theta_t) - M^o)$, where W is a fixed p -by- p -dimensional positive semidefinite weighting matrix and $\bar{M}^s(\theta_t)$ denotes the value of the vector of simulated moments averaged over K simulated data sets, each obtained using the parameter vector θ_t .²² Under the conditions stated in Pakes and Pollard (1989), the MSM estimator is consistent and asymptotically normally distributed.

Estimation uses 265 moments and we estimate 82 parameters. The subjective time discount factor, δ , and the utility curvature parameter, ρ , are identified from information on wealth holdings and saving behavior according to age; knowledge of average wealth is sufficient to identify either δ or ρ , while with additional information on variation in wealth according to age we can identify both parameters. Ordinary Least Squared (OLS) coefficients from regressions of wages and transitions between labor market states on demographic variables provide moments that identify the effects of observed individual characteristics on wages, job offers and involuntary separations. See Appendix B for further details.

As described in Section 3.1, we sample wages only in quarters that coincide with the administration of the annual SOEP survey and only for employed individuals who answered all

²¹In different settings, Alesina and Fuchs-Schuendeln (2007), Fuchs-Schuendeln (2008) and Fuchs-Schuendeln and Schuendeln (2005) also exploit variation generated by German reunification.

²²For the purpose of estimation, we set $K = 5$. We thus simulate the employment, retirement and consumption decisions of around 12000 hypothetical individuals in a total of approximately 200000 time periods. Employing the optimal weighting matrix, that is the inverse covariance matrix of the chosen moments, can lead to small sample bias (see Altonji and Segal, 1996). Therefore, we use a diagonal weighting matrix with diagonal elements equal to the inverse of the variances of the sample moments, estimated by bootstrap re-sampling with clustering at the individual level.

required survey questions. Our estimation strategy accounts for selectivity in wage observations. We therefore represent correctly the financial incentive to work and capture accurately the value of future public pension benefits. In the MSM estimation routine we account to selectivity in wages by matching moments based on sample wage observations with moments constructed using simulated wage draws that have survived the same selection mechanisms as the sample wage observations.²³ A simulated wage draw is included in the construction of the simulated moments if and only if: (i) employment is the individual’s optimal choice in the simulated sample; (ii) the quarter is one in which the individual was surveyed; and (iii) the observation survived random elimination of accepted wage draws designed to account for non-random non-response.²⁴ Non-labor income and non-linearities in the tax and transfer schedules provide exclusion restrictions and thus ensure that identification of the parameters in the wage equation is not reliant purely on functional form.

Appendix C provides further details concerning our treatment of the initial conditions and presents estimates of the parameters that characterize the initial conditions. We note here that the parameters appearing in the initial conditions are estimated jointly with the structural parameters. Further, by including unobservables that may affect both the initial conditions and subsequent behavior, our estimation methodology accounts fully for the endogeneity of the initial observations of individuals’ experience, wages, wealth and employment status.²⁵

4.2 Goodness of Fit and Structural Parameter Estimates

The estimated model is able to fit the observed relationship between life expectancy and retirement. We thus conclude that our model provides a sound basis for counterfactual policy simulations which investigate the effect of life expectancy on life-cycle behavior. In more detail, we obtain a summary measure of the observed relationship between life expectancy and retirement by running an OLS regression of retirement on age 65 life expectancy, age dummies, cohort dummies and time dummies. (We are able to separate cohort effects from the effect of life expectancy due to the presence of differences between demographic groups in the extent of improvements in life expectancy over time.) The coefficient on life expectancy in this OLS regression is -0.066 (with a robust individual-level clustered standard error of 0.027). Meanwhile, the corresponding coefficient on life expectancy implied by the estimated structural model is -0.059, which is less than 0.3 of a standard error away from the corresponding observed quantity.

Our model is also able to replicate observed features of: the distributions of wages and changes in wages; life-cycle labor supply and retirement behavior; the age profile of wealth; and the patterns of transitions between employment and unemployment (see Appendix D).

Table 1 reports the structural parameter estimates. Looking first at the wage equation, we

²³Note that our structural model features the joint determination of wage and employment outcomes and therefore accepted simulated wage offers are subject to the same selectivity as sample wage observations.

²⁴We estimate the probability of an employed individual refusing to answer one or more of the survey questions required to construct the hourly wage. We then exclude the simulated wage draws of employed individuals with the same probability. This method assumes that survey non-response is base purely on observables.

²⁵Health, measured by an indicator of the individual having health problems that limit daily activities, enters the model as a stochastic and exogenous state variable. We estimate the parameters of an equation of motion for health in which an individual’s age t health status is a function of health status in the previous period, age and demographic variables. The parameters from this initial estimation are used to simulate the evolution of health when estimating the parameters of the structural model.

Table 1: Structural parameter estimates

	Coefficient	Standard Error
Wage Equation		
Intercept	1.564	0.076

Probability of Retirement Eligibility on the Grounds of Disability (Υ)		
Intercept	-0.745	0.457
Health problems	0.797	0.414
Male	0.384	0.374

Notes: “Health problems” is an indicator of the individual having health problems that limit daily activities. The mean and standard deviation of the complementarity parameter (η_i) after allowing for truncation are 0.231 (with a standard error of 0.023) and 0.106 (with a standard error of 0.028) respectively.

find that offered wages increase significantly with experience. This finding underlines the importance of experience-based human capital accumulation in the determination of wage offers, and more generally for labor supply behavior over the life-cycle. Offered wages are higher in west Germany than in the east, and native Germans and men receive significantly higher wage offers than immigrants and women respectively. The estimated rate of return to one year of education

is 8.34%. Unobservables are found to play an important role in wage determination. Of the permitted unobservables, the permanent individual effect (α_i) has the highest standard deviation and therefore has the largest impact on wage offers. This finding implies that unobserved differences in wages are driven primarily by differences in permanent unobserved individual characteristics. However, we also find a significant unobserved match-specific effect; quantitatively, we find that each quarter an individual has a 14.8% chance of receiving a new match-specific draw. This corresponds to an individual receiving a new match-specific draw on average every 6.8 quarters.²⁶

The job offer and involuntary separation probabilities display clear age patterns: older individuals are less likely to receive a job offer and are more likely to be subject to an involuntary separation than younger individuals. As expected, those in poor health and those living in east Germany are relatively likely to experience an involuntary separation and are relatively unlikely to receive a job offer. Unobserved individual characteristics have significant effects on the job offer and involuntary separation probabilities. The unobservables affecting job offers and involuntary separations are significantly negatively correlated, a result which is consistent with those unobserved characteristics that contribute positively to involuntary separations also having a negative effect on the probability of receiving a job offer. We find that the probability of being eligible for early retirement on the grounds of disability is positively and significantly (at the 5.4% level) related to the presence of health problems.

The coefficient on consumption, β , is significantly greater than zero which implies that individuals' behavior is influenced by the financial incentives associated with employment, retirement and wealth accumulation. We find that η_i , the individual-specific parameter that describes the complementarity between consumption and leisure, varies significantly over individuals. Moreover, after allowing for truncation of η_i from above at 0.999 and from below at 0, the mean value of η_i is 0.231. This implies that on average 23.1% of consumption is required to compensate an employed individual for the disutility of working. Our estimate of the annualized subjective time discount factor is 0.989, a figure which is in line with previous findings (e.g., De Nardi et al., 2010). Finally, our estimate the CRRA parameter, ρ , is 2.565 and we therefore individuals are risk averse. Both the subjective time discount factor and the CRRA parameter are precisely estimated, which lays testament to the quality and relevance of the available consumption information.

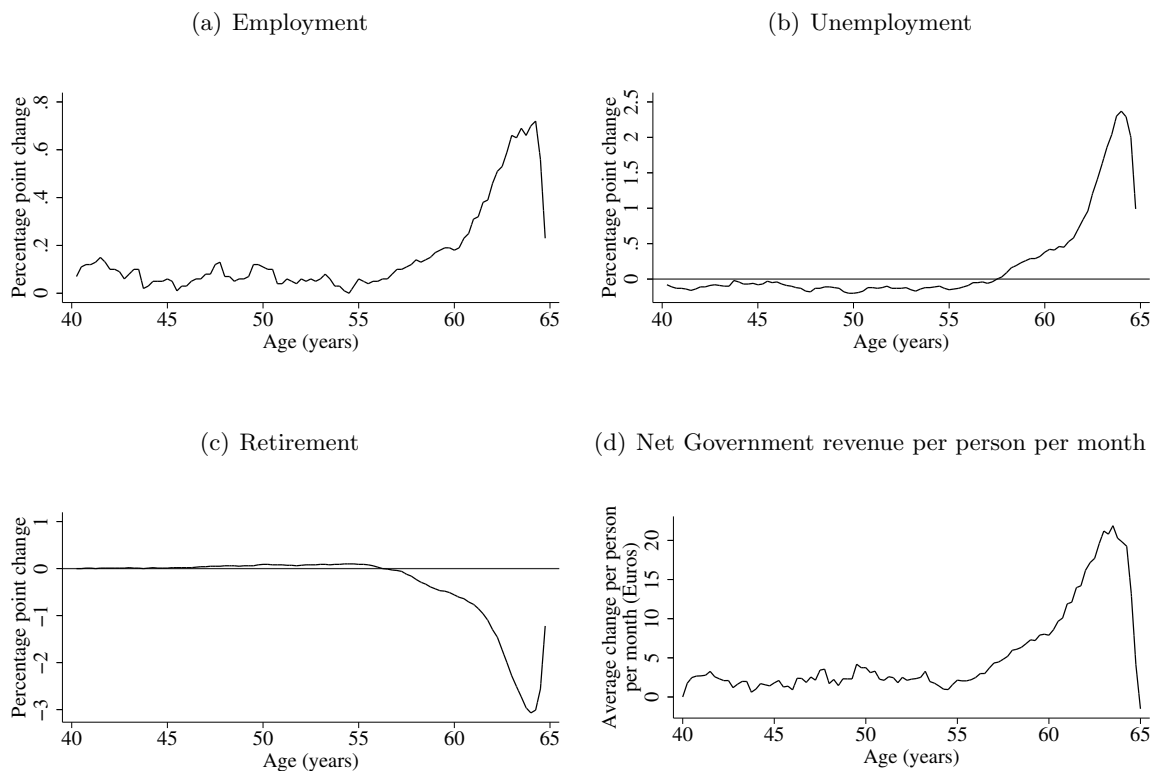

5 Policy Analysis

5.1 Longevity, Life-cycle Behavior and Government Revenue

The behavioral and fiscal implications of increasing life expectancy must be understood prior to determining how public pension systems may be reformed to ensure financial stability in the face of improving longevity. We thus commence our counterfactual analysis by using our estimated structural life-cycle model to explore the effects of an increase in life expectancy. Specifically, we compare the optimal life-cycle behavior, and associated tax, transfer and pension receipts, of

²⁶This results suggests that match-specific wage shocks occur at a higher frequency than job changes. Therefore, we conclude that individuals can experience persistent wage shocks without changing jobs.

Figure 3: Life expectancy improvement between 1942 and 1982 birth cohorts:
Effects over the life-cycle on rates of employment, unemployment and retirement and on net
Government revenue per person per month

Notes: All figures refer to individuals aged 40-64.75 years.

two groups of individuals who differ only with respect to life expectancy. Each individual in the first group is assigned the appropriate gender-specific and region-specific life expectancy of the 1942 birth cohort, that is the life expectancy of an individual from the appropriate demographic group who was 65 years old in 2007. Meanwhile, each individual in the second group is assigned the appropriate predicted individual-specific life expectancy of the 1982 birth cohort, who will reach age 65 years 40 years after individuals in the first group, i.e., in 2047. According to the HMD for Germany, life expectancy at age 65 is anticipated to be on average 6.4 years higher for the 1982 birth cohort than for the 1942 birth cohort.²⁷ For both groups of individuals, we fix the distribution of all characteristics other than life expectancy at that observed in our sample and we impose the year 2007 tax, transfer and pension systems throughout.

Figures 3(a) - 3(c) show how the rates of employment, unemployment and retirement are affected by the 6.4 year increase in age 65 years life expectancy anticipated to occur over the next 40 years. This increase in life expectancy reduces the retirement rate by an average of approximately 1 percentage point for those aged 57-64.75 years and by almost 3 percentage points for individuals aged 64 years. The postponement of retirement among individuals approaching the full pensionable age of 65 years is balanced by an increase in unemployment and, to a

²⁷The corresponding increase in life expectancy at birth over the 40 years that separate these two cohorts is roughly 10 years. Therefore, the anticipated evolution of life expectancy in Germany is broadly in line with the widespread trend in life expectancy in the developed world documented by Oeppen and Vaupel (2002).

Table 2: Life expectancy improvement between 1942 and 1982 birth cohorts:
Effects on average net Government revenue per person, years of employment post age 40 years,
retirement age and weighted pension points upon retirement.

Birth Cohort	Public Pension: FPA/ Pension Value	Average Life Exp. at 65	Net Government Revenue Per Person				Yr Emp. Age \geq 40	Ret. Age	Pension Points

Notes: “FPA” refers to the full pensionable age and “Pension Value” is the per-year value of public pension benefits. “Net Government Revenue Per Person” is the average per person (starting at age 40 years and continuing until death) net revenue received by the Government, measured in Euors. “Yr Emp. Age \geq 40” is the average number of years of employment post age 40 years and “Ret. Age” is the average age of retirement. “Pension Points” is the average number of weighted pension points accumulated prior to the date of retirement.

lesser extent, an increase in employment. There are two factors which lead the postponement of retirement to be balanced predominantly by higher unemployment. First, those wanting to retire later may have difficulty finding a job due to the relatively low rate of job offers and the relatively high rate of involuntary separations experienced by older individuals. Second, the long entitlement period for Unemployment Insurance provide strong incentive for individuals to use unemployment as a stepping-stone into retirement (see Appendix E.2).

Next, we consider the effect of an increase in life expectancy on net Government revenue, NGR, which takes the following form

$$\text{NGR} = \text{Income Tax} + 2 \times \text{SSC} - \text{UIB} - \text{SAB} - \text{Public Pension Benefits}, \quad (16)$$

where Income Tax consists of taxes paid on labor income, pension income and interest income from wealth holdings, SSC denotes individual Social Security Contributions (this figure is multiplied by two because firms must match individuals’ contributions), and UIB and SAB correspond respectively to Unemployment Insurance benefits and Social Assistance benefits. Figure 3(d) shows that the increase in public pension demands associated with longer life expectancy is offset partly by higher revenue receipts from individuals aged below the full pensionable age. Net Government revenue per person increases at every age prior to the full pensionable age of 65 years. Reflecting the age profile of responses in labor supply and retirement, we find the largest increase in net Government revenue for individuals aged 64 years.

We now extend our analysis of the fiscal effects of an increase in life expectancy by additionally considering net transfers made to individuals aged at or above the full pensionable age of 65 years. Based on the estimated model, we determine the net transfer made to the Government by each individual in each quarter of his or her life, starting at age 40 years and continuing until death. Summing over an individual’s life yields the total post age 40 years net transfer made by the individual to the Government. Finally, averaging over individuals provides an estimate of average per-person net Government revenue. Table 2 shows that the 6.4 year increase in life expectancy anticipated to occur over the next 40 years causes average per-person net Government revenue to decrease by 75451 Euros. Decomposing, the increase in life expectancy under consideration has a minor positive effect on the average transfer made to unemployed individuals, and causes net Government revenue received from employed individuals to increase by an average of 6418 Euros per person. However, the average net transfer made to retired individuals

Table 3: Life expectancy improvement between 1942 and 1982 birth cohorts:
Implications for wealth accumulation and consumption

Birth Cohort	Public Pension: FPA/Pension Value	Wealth on Retirement	Monthly Income from Wealth	Total Cons. post Age 40	Monthly Consumption		
					Age 45	Age 55	FPA (Age 65)
1942	65/ 2007 System	27371	146	571197	1291	1341	1054
1982	65/ 2007 System	28402	126	665166	1294	1336	1035
Difference (1982 – 1942 cohort):		1031	-20	93969	3	-5	-19

Notes: “Wealth on Retirement” is average per-person private wealth at the date of retirement. “Monthly Income from Wealth” is the average per-person actuarially fair monthly annuity income wealth at the date of retirement. Consumption (Cons.) figures are averaged over individuals. Consumption and wealth figures are in Euros. “FPA” refers to the full pensionable age.

increase by 80556 Euros per person.

Last, we analyze the effect of life expectancy on consumption choices and wealth accumulation. In response to an increase in life expectancy, optimizing individuals adjust consumption to equalize the higher return to saving with marginal utility of contemporaneous consumption, which in turn depends on current employment behavior. Empirically, Table 3 shows that the considered 6.4 year increase in age 65 life expectancy leads average individual wealth at the date of retirement to increase by 1031 Euros.²⁸ This result, which is in line with the findings of De Nardi et al. (2009) and De Nardi et al. (2010), demonstrates that the ability to alter wealth accumulation decisions provides individuals with a valuable means of adjusting behavior in response to an improvement in longevity. Recognition of this fact is necessary for understanding the effects of reductions in the generosity of the public pension system, discussed below in Section 5.2.

Table 3 further shows that the increase in life expectancy anticipated to occur between the 1942 and 1982 birth cohorts leads to a 21 Euros per month fall in the income stream that retired individuals are able to obtain from accumulated wealth. Thus, increased wealth accumulation prior to retirement is insufficient to compensate for the effect of higher life expectancy on the feasible income stream obtainable from wealth holdings. Due to increased pension point accumulation prior to retirement, we find that the considered increase in age 65 life expectancy causes average monthly consumption at age 65 years and above to fall by slightly less than the decline in the feasible income stream obtainable from accumulated wealth. Specifically, consumption at age 65 years and above falls by an average of 19 Euros per month.

Notwithstanding the fall in the average monthly consumption of retired individuals, the 6.4 year increase in age 65 years life expectancy anticipated to occur between the 1942 and 1982 birth cohorts causes expected total per-person post age 40 years consumption to increase by approximately 94000 Euros. As shown in Table 2, roughly 75000 Euros of this increase is accounted for by increased transfers from the Government. Meanwhile, the remaining 19000 Euros of this increase is financed from increased wage income and additional interest income from wealth. Indeed, one of the effects of the improvement in longevity under study is to cause the survival rate prior to the full pensionable age of 65 years to increase. Holding fixed employment and retirement choices, this change leads to an increase in expected life-time wage income.

²⁸This effect consists of a component arising from changes in savings decisions and a component due to alterations in the timing of entry into retirement.

5.2 Public Pension Reform

The substantial deterioration in the Government's budgetary position created by an increase in life expectancy suggests an important role for public pension reforms. With this in mind, we consider the 6.4 year increase in age 65 life expectancy anticipated to occur over the 40 years that separate the 1942 and 1982 birth cohorts and we analyze the behavioral and fiscal effects of: (i) increases in the full pensionable age; and (ii) cuts in the per-year value of public pension benefits. Throughout this analysis, we continue to fix the distribution of all characteristics other than life expectancy at that observed in our sample and we impose the year 2007 tax and transfer systems. Unless otherwise indicated, we use the 2007 public pension system.

The top panel of Table 4 summarizes the effects on labor market behavior and net Government revenue of increasing the full pensionable age from its current value of 65 years.²⁹ We find that increases in the full pensionable lead individuals to postpone retirement and to increase years of employment prior to retirement. Within the range of reforms under consideration, a one year increase in the full pensionable age causes the average retirement age to increase by approximately 0.9 of a year, and causes average years of employment prior to retirement to increase by 0.85 of a year. The strong dependence of the employment rate on the age-based eligibility requirements of the public pension system demonstrates that, for many individuals, the rules that control access to public pension benefits are binding constraints on behavior. This finding is entirely consistent with the specifics of the institutional rules. Indeed, according to the 2007 public pension system, for the vast majority of individuals, retirement prior to the full pensionable age either was not possible or was associated with reduced public pension benefits (see Appendix F.3). An increase in the full pensionable age, and the associated age-based eligibility requirements, therefore raises the age at which most individuals can receive public pension benefits of a given level of generosity.

In terms of fiscal effects, we find that increases in the full pensionable lead to appreciable increases in the average net transfer made to the Government from employed individuals, and cause substantial reductions in the average transfer payment made to retired individuals. Overall, our calculations suggest that the full pensionable age must be increased to 69.34 years to offset the fiscal consequences for the Government of 40 years worth of growth in life expectancy. In other words, a 6.4 year increase in age 65 life expectancy requires that the full pensionable age be increased by 4.34 years in order to restore the Government's budgetary position.³⁰ This policy eliminates the approximately 75000 Euros per-person deficit created by 40 years worth of growth in life expectancy via two main routes. First, an increase of 4.34 years in the full pensionable age increases the net transfer received by the Government from employed individuals by an average of approximately 54000 Euros per person. Second, the net transfer made to retired individuals declines by an average of roughly 23000 Euros per person.

The bottom panel of Table 4 summarizes the effects on labor market behavior and net Government revenue of cuts in the per-year value of public pension benefits. Throughout these

²⁹When conducting this analysis the age-based requirements for early retirement were increased in line with the increase in the full pensionable age.

³⁰This figure was obtained by computing the net Government revenue associated with full pensionable ages of 69.25 years and 69.5 years and then interpolating linearly to find the increase in the full pensionable age that offsets exactly the fiscal consequences of 40 years worth of growth in life expectancy.

Table 4: Public pension reforms:

Effects on average net Government revenue per person, years of employment post age 40 years, retirement age and weighted pension points upon retirement

Birth Cohort	Public Pension: FPA/Pension Value	Net Government Revenue Per Person				Yr Emp. Age \geq 40	Ret. Age	Pension Points

Notes: See Table 2.

calculations the full pensionable age is held fixed at its current value of 65 years. This set of reforms has little effect on employment outcomes. Further, cuts in the per year value of public pension benefits have only a minor postponement effect on retirement: we find that the average age of retirement increases by 0.20 of a year for every 5 percentage point cut in the per-year value of public pension benefits. These behavior adjustments reflect partly that high wage individuals are most affected by a cut in the per-year value of public pension benefits. Such individuals are likely to be employment, and hence are generally unable to increase employment. Furthermore, a cut in the per-year value of public pension benefits has an ambiguous effect on employment and retirement incentives: A cut in the per-year value of public pension benefits reduces expected income in retirement for while simultaneously cutting future returns to current employment - the associated income and substitution effects work in opposite directions. Thus, even when affected individuals are in a position to adjust behavior, the realized behavior response may be small, as is the case here. Cuts in the per-year value of public pension benefits cause net Government revenue to increase due to considerably lower net transfers to retired individuals. We find that the per-period value of public pension benefits must be reduced by 37.7% in order to counterbalance the fiscal consequences of 40 years worth of growth in life expectancy.

We conclude our analysis of public pension reforms with Table 5, which explores the effects of increases in the full pensionable age and cuts in the per-year value of public pension benefits on individuals' wealth accumulation and consumption behavior. Mirroring the different responses of labor supply and retirement, we find that the two reforms have distinctly different implications for wealth accumulation and consumption behavior.

Increases in the full pensionable age have little effect on wealth at the date of retirement or on consumption at ages 45 or 55 years; the main means by which individuals re-optimize in

Table 5: Public pension reforms:

Notes: See Table 3.

response to an increase in the full pensionable age are adjustments in employment retirement choices (see Table 4). This result can be understood as follows. Increases in the full pensionable age create strong incentives for individuals to postpone retirement and to increase employment, and thereby lead to higher public pension benefits upon retirement. (Recall that public pension benefits in retirement are directly proportional to the individual's stock of pension points which, in turn, is incremented for each and every year of employment or Unemployment Insurance eligible unemployment). In this sense, this reform actually reduces the incentive for individuals save privately retirement. However, the individuals whose retirement plans are most severely affected by an increase in the full pensionable age are predominantly those individuals with little or no personal wealth (as wealthy individuals are relatively unlikely to be constrained by the institutional rules). Possibilities for wealth decumulation among the affected individuals are therefore limited.

Increases in the full pensionable cause expected total post age 40 years consumption to increase, a change that can be linked to increased consumption among retirees. Quantitatively, consumption at the full pensionable age, i.e., the first date at which all individuals are necessarily retired, increases by an average of 122 Euros per month when the full pensionable age is increased from 65 years to 71 years. This change reflects predominantly the returns to higher life-cycle employment which occur through the intertemporal linkages present in the public pension system. Increased income from wealth also contributes to the higher average consumption of retirees, however the magnitude of this effect is relatively small.

In contrast, as illustrated in the bottom panel of Table 5, we find that cuts in the per-year value of public pension benefits have a dramatic positive effect on wealth accumulation: for the reforms under consideration, each 5 percentage point cut in the per-year value of public pension benefits leads average wealth accumulated at the date of retirement to increase by over 1000

Euros per person. Moreover, given the modest effect of cuts in the per-year value of public pension benefits on the timing of retirement, increased wealth accumulation translates into a higher feasible income stream obtainable upon retirement from accumulated wealth. These large responses in savings behavior reflect that, *ceteris paribus*, a cut in the per-year value of public pension benefits mechanically increases the marginal utility of income from wealth in retirement. Combined with the theoretically ambiguous and empirically small effect of this reform on labor supply and retirement behavior, it is natural that the predominant behavioral effect of a cut in the per-year value of public pension benefits is to cause an increase in wealth accumulation. However, we find that increased wealth accumulation prior to retirement is not sufficient to counter the income effects of a cut in the per-year value of public pension benefits, irrespective of the size of the cut. Therefore, following a cut in the per-year value of public pension benefits, monthly consumption at the full pensionable age decreases, as does expected total post age 40 years consumption.

In summary, an increase in the full pensionable age of 4.34 years and a cut in the per-year value of public pension benefits of 37.7% both neutralize the effect on the Government's net revenue position of the 6.4 year increase in age 65 life expectancy anticipated to occur during the 40 years that separate the 1942 and 1982 birth cohorts. However, these two revenue-equivalent policy approaches have dramatically different implications for individuals' labor supply and retirement behavior, for wealth accumulation and for consumption outcomes. Notably, reinstating the Government's budgetary position by increasing the full pensionable age leads to a higher average retirement age and a higher employment rate as compared to if the Government's budgetary position is reinstated by cutting the per-year value of public pension benefits; however, cutting the per-year value of public pension benefits has a much larger effect on wealth accumulation than does increasing in the full pensionable age. Of these two revenue-equivalent policies, expected total post age 40 years consumption is highest following the increase in the full pensionable age. We conclude, therefore, that a reduction in public pension generosity operationalized via an increase in the full pensionable age generates a greater increase in productivity than a revenue-equivalent reform which entails a cut in the per-year value of public pension benefits.

6 Conclusion

Life expectancy in the developed world is anticipated to increase appreciably over the coming decades. In Germany, for example, life expectancy at age 65 years is projected to increase by 6.4 years over the next 40 years. This substantial demographic change poses a threat to the sustainability of many defined benefit public pension systems. Using a rich dynamic structural life-cycle model estimated using the Method of Simulated Moments, this paper has provided new insights into the effect of life expectancy on life-cycle behavior. Furthermore, by recognizing the dependency between life-cycle behavior, life expectancy, and the public pension system, we have demonstrated how public pensions systems can be reformed effectively to ensure financial viability despite increasing life expectancy.

Our results contain several lessons for policy makers contemplating public pension reforms. At the highest level of generality, our analysis speaks to the particular importance of determining the severity of public pension reforms specifically for individuals who are able, forced or inclined

to adjust behavior in response to the reform. For example, our results show that, in the case of Germany, positive employment effects are obtained when the age-based eligibility thresholds for public pension benefits are increased but not when the per-year value of public pension benefits is cut. This result reflects that the age-based eligibility rules are binding constraints for many individuals. Meanwhile, cuts in the per-year value of public pension benefits are felt most by individuals with limited scope to increase work intensity due to their ex ante strong attachment to the labor market.

Beyond to making a significant contribution to the current policy debate on public pension reform, this paper has provided several insights regarding the analysis of individual behavior over the life-cycle. Notably, we have shown that the incentives created by the pension system are important for explaining individuals' life-cycle employment, retirement and consumption decisions. We conclude, therefore, that a detailed depiction of the pension system should be central to the modeling of many aspects of life-cycle behavior. Perhaps more importantly, the results of our counterfactual policy simulations have demonstrated that life expectancy has quantitatively meaningful implications for optimal behavior prior to the full pensionable age. Our analysis thus suggests that an accurate understanding of the fiscal and behavioral implications of improving longevity requires a life-cycle approach which permits behavioral responses in terms of employment, retirement and consumption. Life-cycle modeling has been used previously to understand the implications of life expectancy for decisions related to wealth accumulation. This paper has explored the dependence of employment and retirement decisions, as well as consumption choices, on life expectancy. Our analysis therefore extends previous research along an important dimension.

Appendix

A Value Function Approximation

Our method for approximating the value functions appearing in the life-cycle optimization problem is based on recursive simulation and interpolation, as first introduced by Keane and Wolpin (1994). In particular, we start with a set of randomly selected grid of points, where each grid point represents a particular combination of age 64.75 years state variables and an age 64.75 employment and consumption choice. The age 64.75 years state variables are then updated to the age 65 years values in accordance with the evolution of the underlying variables as specified by the structural model. Next, we evaluate the age 65 years value function at each point in the grid of age 65 years state space points; at age 65 years all individuals are retired and therefore computation of the age 65 years value function is straight forward and follows from equation (13). The results of an Ordinary Least Squares (OLS) regression are used to express the expected age 65 years value function in terms of variables known to the individual at age 64.75 years. This OLS regression, as well as those used in later value function approximations, includes a total of 143 regressors and is implemented using a grid containing 5000 points.

At the next stage of the value function approximation, we move back one quarter to age 64.5 years, update the state space variables to the age 64.75 values, and compute the age 64.75 years value function associated with each age 64.75 years choice possibility. Consumption, or equivalently, savings, is a continuous choice variable and therefore implementation of this method requires discretization of the choice set. We achieve this by restricting attention to the following choices: (i) employment in conjunction with savings of -500, 0, 500, 1000 and 2000 Euros per month; (ii) unemployment in conjunction with savings of -2000, -1000, -500, 0, and 500 Euros per month; and (iii) retirement. We construct the choice set to over-represent dissaving combined with unemployment and saving combined with employment because these are the most prevalent combinations of savings and labor supply choices. We replace the expected age 65 years value function appearing in the age 64.75 choice-specific value functions with the approximation obtained previously. The maximum of the age 64.75 years choice-specific value functions is regressed on variables known to the individual at age 64.5 years. The regression results express the expected maximum of the age 64.75 years choice-specific value functions in terms of variables known to the individual at age 64.5 years. We continue backwards recursively in this way until we reach age 40 years. To ensure that we capture the year-specific aspects of the fiscal legislation, this entire procedure is repeated for each of the 17 different tax and transfer systems operational during the sample period.

B Moments

Table 6: Summary of moments

Description of moments	Number of moments	Primarily identifying
Wealth over the life-cycle: age-specific wealth levels and wealth levels by gender and region	29	Subjective time discount factor (δ) and curvature parameter (ρ)
Coefficients from an OLS regression of annual wealth change on age	2	As above
Coefficient on life expectancy from an OLS regression of retirement on life expectancy and controls for gender, region, education, cohort and age	1	As above
Coefficients from an OLS regression of log wages on experience, health, initial employment, region, education, nationality, gender and age terms	14	Distribution of offered wages
Distribution of log wages: percentiles of log wages and annual changes in log wages; 1 st 2 nd and 3 rd order autocorrelations in annual log wages	19	As above
Treatment effects obtained from OLS regressions of transitions between labor market states on the change in UI entitlement period caused by the 1997 UI reform (see Haan and Prowse, 2010)	20	Coefficient on consumption (β)
Coefficients on initial employment state from OLS regressions of employment and retirement on initial employment state	2	Variance of complementarity between consumption and leisure (σ_η)
Persistence in labor market status: frequencies of various sequences of transitions	18	Parameters appearing in the job offer and involuntary separation probabilities
Labor supply over the life-cycle: age-specific employment and retirement rates	50	Mean of the complementarity parameter (μ_η) and age effects in the job offer and involuntary separation probabilities
Coefficients from OLS regressions of the individual-specific numbers of transitions from unemployment to employment and from employment to unemployment on initial employment state; Correlation between individual-specific numbers of transition into and out of employment	3	Variance-covariance matrix of the individual-specific unobservables in the job offer and involuntary separation probabilities (Σ^η)
Coefficients from OLS regressions of transitions from unemployment to employment and from unemployment to retirement on experience, health, UI entitlement period, region, and age terms	30	Parameters determining eligibility for early retirement on the grounds of disability
Coefficients from OLS regressions of transitions from employment to unemployment and from employment to retirement on experience, health, UI entitlement period, region, and age terms	28	As above
Coefficients from OLS regressions of initial employment and initial retirement on initial experience, initial health, gender, region, education, nationality, children, marital status, age terms and cohort effects	38	Parameters describing initial employment and initial retirement (see Appendix C)
Coefficients from an OLS regression of initial wealth on initial employment, initial experience, gender, region and age terms; Standard deviation of initial wealth	11	Parameters describing initial wealth (see Appendix C)

Notes: In the above descriptions of regressors, “region” is an indicator of the individual residing in west Germany. “Health” is an indicator of the individual having health problems that limit daily activities. “Gender” is an indicator of the individual being male. “Education” refers to years of education. “Nationality” is an indicator of the individual being a native German. “Children” and “marital status” are indicators of, respectively, the individual having had dependent children prior to entering the sample and having been married prior to entering the sample. “UI” is an abbreviation for Unemployment Insurance.

C Initial Conditions

The intertemporal linkages in our model, arising from the public pension and Unemployment Insurance systems, the endogenous accumulation of experience, and employment state dependent job opportunities, imply that in-sample wages and employment outcomes depend on the initial observations of experience, wages, wealth and employment status. Moreover, the presence of persistent unobservables in wages, in preferences and in the job offer and involuntary separation probabilities renders the first observations of experience, wages, wealth and employment status endogenous with respect to the persistent unobservables that drive subsequent behavior. To obtain consistent estimates of the structural parameters, despite the endogeneity of the initial conditions, we proceed in the spirit of Heckman (1981). Specifically, we approximate behavior prior to the sample period using a reduced form model in which the pre-sample endogenous variables may depend on the persistent unobservables that affect behavior during the sample period. The parameters appearing in the initial conditions are estimated jointly with the structural parameters.

When implementing our MSM estimation method, we simulate employment and retirement outcomes for each individual in each quarter between leaving full-time education and entering the sample from a multinomial logit model. The payoffs in the multinomial logit model depend on observed individual characteristics, the quarter-specific wage, cohort effects, and the permanent unobservables that feature in preferences and in the job offer and involuntary separation probabilities. When simulating behavior prior to the sample period, quarter-specific wages are obtained by taking draws from the distribution of offered wages as described by the structural parameters. Using the simulated pre-sample employment outcomes and wages we are able to construct each individual's experience, Unemployment Insurance entitlement period and pension points at the time when the individual enters the sample. Finally, we simulate initial wealth by drawing from a log normal distribution with a variance σ_{Wealth}^2 and a mean that depends on the individual's initial experience and initial employment state, as well as on age, gender, education and region of residence. Note that, via dependencies on pre-sample employment behavior and wages, the simulated values of initial experience, the initial Unemployment Insurance entitlement period, initial pension points and initial wealth are endogenous with respect to behavior during the sample period.

Marital status and household structure prior to the individual entering the sample perform the role of exclusion restrictions, that is variables that affect the initial conditions but which, conditional on initial behavior, do not affect outcomes during the sample period. Examination of the relevant moments reveals that the excluded variables jointly have a significant effect on initial employment and initial retirement behavior (χ^2 test; $p = 0.001$). Table 7 presents our estimates of the parameters appearing in the initial conditions.

Notes: $P_j(w^*)$ refers to the j^{th} percentile of log wages and $P_j(\Delta^r w^*)$ denotes the j^{th} percentile of the r^{th} annual difference in log wages. “Observed” refers to a value observed in the sample while “Fitted” refers to the value of the applicable quantity averaged over 5 simulated data sets. “SE” is the standard error of the observed quantity (obtained via bootstrapping with clustering at the individual level) and “t-value” is the t-value for the test of equality of the observed and fitted quantities.

E Tax and Transfer Systems

E.1 Net Income if Employed

An employed individual receives a gross income equal to the total value of gross wage income and interest income from wealth, with the latter being equal to the real interest rate times the value of the individual’s stock of wealth. The net income received by an employed individual aged t , $m_{i,f,t}$, is computed by applying to gross income the appropriate deductions for Social Security Contributions and income tax.

Social Security Contributions are made for health, pension and Unemployment Insurance benefits and are obligatory. Social Security Contributions are payable at a constant rate on all

gross wage income above a disregard and below an earnings cap. Social Security Contributions are not payable on any gross wage income in excess of the earnings cap. In addition to the employee's Social Security Contributions, the employer pays the same amount in Social Security Contributions.³¹ Income tax is payable on the entirety of an individual's taxable income. Taxable income, in turn, consists of any gross income in excess of the sum of the universal tax-free allowance and permissible Social Security Contributions.³² Income tax is payable at a rate that is increasing in the individual's taxable income.³³ Table 9 summarizes some key features of tax and transfer systems.

Table 9: Selected features of the German tax and transfer systems: 1991 - 2007

Year	Social Security Contributions			Income tax			Social Assistance	
	Contribution rate (%)	Max. Cont. west per month	Max. Cont. east per month	Tax free allowance per year	Top marginal tax rate (%)	Solidarity tax (%)	Average west per month	Average east per month
1991	17.7	3250	1700	4050	53	3.3	550	500
1992	18.4	3400	2400	4050	53	3.75	540	520
1993	18.6	3600	2650	4050	53	0	550	544
1994	19.4	3800	2950	4050	53	0	557	545
1995	19.6	3900	3200	4050	53	7.5	564	553
1996	20.1	4000	3400	6021	53	7.5	571	560.5
1997	21.0	4100	3550	6021	53	7.5	580	569.5
1998	21.1	4200	3500	6156	53	5.5	586	575
1999	21.1	4250	3600	6507	53	5.5	594	584
2000	20.5	4300	3550	6876	51	5.5	606	596
2001	20.4	4350	3650	7200	48.5	5.5	617	606
2002	20.6	4500	3750	7200	48.5	5.5	629	617
2003	21.0	5100	4250	7200	48.5	5.5	634	622
2004	21.0	5150	4350	7632	45	5.5	643	631
2005	20.7	5200	4400	7632	42	5.5	653	637
2006	21.0	5250	4400	7632	42	5.5	658	642
2007	20.3	5250	4550	7632	45	5.5	662	645

Notes: Unless indicated otherwise, all figures are in Euros and are expressed in nominal terms. Social Assistance consists of a person-related component that varies by region of residence and individual-specific housing benefits. Housing benefits are limited to the cost of a reasonable apartment, given local property prices and household size.

E.2 Net Income if Unemployed

An unemployed individual receives a gross income equal to the value of interest income from wealth. The net income received by an unemployed individual aged t , $m_{i,u,t}$, is computed by adding to gross income any transfer payments from the Government and applying the appropriate deduction for income tax. Government-provided transfers to unemployed individuals take two forms: Means-tested Social Assistance benefits which ensure a universal minimum income, irrespective of the individual's employment or earnings history; and Unemployment Insurance

³¹Since July 2005 there has been a small divergence from this rule which we neglect in this study.

³²The value of Social Security Contributions that can be set against gross income when computing taxable income is subject to a maximum limit.

³³We note here two further features of income tax that apply irrespective of an individual's labor market status. First, only interest income from wealth in excess of a disregard counts towards taxable income. Second, there exists a Solidarity tax which was introduced to finance the cost of German reunification. The Solidarity tax is proportional to an individual's income tax liability. Currently, there is no indication that the Solidarity tax will be phased out.

benefits which provide an unemployed individual with a fraction of his or her previous net earnings. Social Assistance benefits are paid indefinitely while Unemployment Insurance benefits are paid for an entitlement period which is determined by an individual's age and recent employment history. Social Assistance benefits have no tax implications. Unemployment Insurance benefits are not directly taxed. Instead, Unemployment Insurance benefits are added to interest income and the individual's average tax rate is determined based on the same tax schedule as applicable to employed individuals. The individual's tax liability is determined by applying the individual-specific average tax rate to interest income. Table 10 provides further details concerning the Unemployment Insurance system.

Table 10: Maximum Unemployment Insurance entitlement period by age: 1991 - 2007

Age (years)	Prior to April 1997	From April 1997 until Jan 2006	Since February 2006
< 42	12	12	12
42-43	18	12	12
44	22	12	12
45-46	22	18	12
47-48	22	22	12
49-51	26	22	12
52-53	26	26	12
54	32	26	12
55-56	32	26	18
≥ 57	32	32	18

Notes: Adapted from Schmitz and Steiner (2007). Individuals accumulate entitlement to Unemployment Insurance benefits at a rate of one month of Unemployment Insurance entitlement for every two months of employment, up to the relevant age-specific maximum detailed in this table. For the duration of the entitlement period, Unemployment Insurance benefits provide an income of up to 60% of an individual's net income in his or her most recent job.

F Public Pension System: Further Details

F.1 Accumulation of Pension Points

In addition to the pension point accumulation methods detailed in Section 2.4, individuals may be awarded further pension points in recognition of child-rearing. Specifically, one parent, normally the mother, is credited with one pension point for each child born before 1992 and three pension points for each child born more recently. Although we restrict our sample to men and women who are currently living without dependent children, it is possible that members of our sample previously cared for children. Reflecting the possibilities for individuals to gain pension points for child-rearing, in the empirical implementation of the model we credit all women who had at least one child prior to entering the sample with 3 additional pension points. The German legislation further specifies that individuals may be awarded additional pension points for vocational training, university education, military or community service and provision of care for relatives. We neglect these additional pension points in our analysis.

F.2 Pension Point Values

Table 11 shows the proportionality factors used to compute the value of the non-reduced public pension. This table also shows the adjustment factor applied the wages of east Germans prior to determining the pension point weight.

Table 11: Pension point values (proportionality factors): 1991 - 2007

Year	Point value in Euros		Adjustment factor for east Germany
	West Germany	East Germany	
1991	20.74 (25.32)	13.59 (15.78)	1.37
1992	21.80 (25.32)	13.59 (15.78)	1.44
1993	22.75 (25.31)	16.45 (18.30)	1.32
1994	23.52 (25.48)	17.63 (19.10)	1.27
1995	23.64 (25.16)	18.58 (19.79)	1.23
1996	23.86 (25.04)	19.62 (20.59)	1.22
1997	24.26 (24.76)	20.71 (21.33)	1.21
1998	24.36 (24.71)	20.90 (21.33)	1.21
1999	24.69 (24.69)	21.48 (21.78)	1.21
2000	24.84 (24.35)	21.61 (21.61)	1.20
2001	25.31 (24.48)	22.06 (21.63)	1.20
2002	25.86 (24.75)	22.70 (21.95)	1.20
2003	26.13 (24.60)	22.97 (21.98)	1.19
2004	26.13 (24.13)	22.97 (21.63)	1.19
2005	26.13 (23.75)	22.97 (21.21)	1.18
2006	26.13 (23.75)	22.97 (20.88)	1.18
2007	26.27 (23.33)	23.09 (20.51)	1.18

Notes: Non-parenthesized figures are nominal and figures in parentheses have been converted into year 2000 prices using the Retail Price Index.

F.3 Eligibility for Early Retirement and Adjustments to Public Pension Benefits for Early Retirees

As noted in Section 2.4, the eligibility criteria for early retirement depend on gender, disability status, working history and age. We provide here further details regarding the eligibility criteria for early retirement. In addition, we describe the year-specific rules that define the value of public pension benefits received by early retirees. We reiterate that all of these details are fully incorporated into our implementation of the above described structural life-cycle model.

Individuals aged under 60 years who are able to demonstrate sufficiently poor health can receive a disability pension. The value of the disability pension is proportional to the cumulative value of the weighted pension points that the individual would have received if he or she had remained in employment until age 60 years, with the proportionality factor being the same as that used to determine the value of public pension benefits for individuals retiring at the full pensionable age. Additionally, individuals aged over 60 years who are able to demonstrate sufficiently poor health can take early retirement and thus claim public pension benefits. Prior to 2002, such individuals received a “non-reduced public pension”, the value of which is obtained by multiplying the individual’s weighted pension points accumulated at the time of retirement by the same proportionality factor as used to determine the value of public pension benefits for individuals retiring at the full pensionable age. More recently, the non-reduced public pension has only been available to individuals with sufficiently poor health aged 63 years or over at the date of retirement. Meanwhile, those entering early retirement between the ages of 60 and 63 years due to poor health have received a reduced public pension. The value of the reduced public pension is obtained by applying a penalty to the non-reduced pension of 3.6% for every year that the individual’s age upon retirement is below the full pensionable age of 65 years. This adjustment is less than actuarially fair.

In addition, prior to 1999, women aged 60 years and above and men with sufficiently long service histories (defined as at least 35 years of work experience) aged 63 years or over at the date

of retirement were able to retire and receive a non-reduced public pension. Legislative reforms in 1992 and 1999 increased the age requirement for retirement on a non-reduced public pension to 65 years for healthy men and women, and also introduced the right to early retirement from age 60 years on a reduced public pension for individuals with long service histories. The value of the reduced public pension is obtained by applying a penalty of 3.6% to the non-reduced pension for every year that the individual's age upon retirement is below the full pensionable age of 65 years. The phase-in period for the 1992 legislation commenced in 1997 and the combined 1992 and 1999 reforms will be fully effective by 2017. See Bonin (2009) for further details.

F.4 Expectations Concerning the Future Public Pension System

As explained in footnote 10, we assume that individuals expect the cohort-specific rules that define the public pension system will be maintained. We describe here the public pension reforms that occurred during the sample period and we argue that our modeling approach does not neglect any important anticipated future changes in the public pension system.

Recent pension reforms have the potential to alter the generosity of future public pension benefits. Specifically, recent reforms have: (i) increased the full pensionable age from 65 to 67 years; (ii) changed the eligibility requirements for early retirement and reduced the generosity of the public pension for some groups of early retirees; and (iii) changed the value of the proportionality factor, via the introduction of a “sustainability factor”. The increase in the full pensionable age affected only a handful of the sampled individuals and only in the second half of 2007. Thus, we assume reasonably a full pensionable age of 65 years for all sample members. Regarding the treatment of those who wish to retire early, we note that reforms to either the rules governing eligibility for early retirement or the adjustments made to the value of public pension benefits received by early retirees have always been announced many years in advance of implementation. Therefore, these changes did not affect the pension system applicable to individuals aged over 40 years at the time of announcement. It is therefore entirely realistic for us to assume that the sample members, who are all aged 40 years or above, expect that the rules applicable to their particular birth cohort will persist.

Finally, the sustainability factor, introduced in 2005, constitutes an adjustment to the proportionality factor and is designed to allow the public pension system to accommodate demographic changes and business cycle effects. Specifically, the sustainability factor depends on the ratio of the earnings of working individuals to the number of retired individuals, and acts to reduce the generosity of public pension benefits if this ratio decreases. It is anticipated that in the long-run the sustainability factor will work to reduce the value of public pension benefits. However, the short-run effects of the sustainability factor are unclear. Indeed, via the sustainability factor, a recent rise in female labor force participation caused an increase in the value of public pension benefits. We therefore consider it unlikely that the introduction of the sustainability factor will thus far have affected strongly individuals' expectations concerning future public pension benefits. Moreover, the sustainability factor was introduced in 2005, which is towards the end of our sample period. For these reasons, we neglect the sustainability factor in our analysis.
