Univariate Unobserved-Component Model with a Non-Random-Walk Permanent Component*

Zhiwei Xu†

Abstract

In this note, we revisit the univariate unobserved-component (UC) model of U.S. GDP by relaxing the traditional random-walk assumption of the permanent component. Since our general UC model is unidentified, we investigate the upper bound of the contribution of the transitory component, and find the GDP fluctuation is dominated by the permanent component.

Keywords: Unobserved-Component Model; Random-Walk Assumption; Permanent and Transitory Shocks

1. Introduction

Morley et al. (2003) study the equivalence of univariate unobserved-component (UC) model and the Beveridge-Nelson (BN) (1981) decomposition. They conclude that the permanent component of U.S. GDP extracted by UC model is exactly the same as the BN trend. The innovations of the two (permanent and transitory) components are highly negatively correlated (further discussions about this point can be found in a recent paper by Oh et al., 2008). The non-orthogonality of the two innovations is mainly caused by the random-walk assumption imposed on the permanent component, see Nagakura (2008) for the formal discussion. In this note, we relax the random-walk assumption by allowing the permanent component to follow a general unit root process. Under our assumption, the real GDP can be decomposed into two orthogonal parts so that the impulse responses to permanent and transitory shocks can be implemented. Since our generalization of the random-walk assumption increases the parameter set of the UC model, the model becomes unidentified. However, we can investigate the upper bound of the contribution of the transitory component to GDP and study the dynamics of this extreme case by implementing impulse response and variance decomposition. We find that the transitory component explains less than 35% of output volatility, therefore the permanent component is the main source of the GDP fluctuation.

2. The UC Model

Our modified UC representation takes the form,

\[\begin{align*}
y_t &= g_t + c_t, \\
g_t &= \mu + g_{t-1} + \frac{\Theta_{q_1}(L)}{\Phi_{p_1}(L)} \eta_t, \quad \eta \sim i.i.d. N(0, \sigma_\eta^2), \\
c_t &= \frac{\Theta_{q_2}(L)}{\Phi_{p_2}(L)} \varepsilon_t, \quad \varepsilon \sim i.i.d. N(0, \sigma_\varepsilon^2),
\end{align*}\]

where \(\{y_t\}\) is log real GDP, \(\{g_t\}\) is an unobserved permanent component with a unit root (i.e., its first difference is a ARMA\((p_1,q_1)\) process with drift \(\mu\)). The unobserved transitory component \(\{c_t\}\) is a stationary ARMA\((p_2,q_2)\) process. Moreover, we assume the two innovations satisfy

\[cov(\eta_t, \varepsilon_{t+k}) = \begin{cases} 
\sigma_{\eta \varepsilon} & \text{for } k = 0 \\
0 & \text{otherwise}
\end{cases}.\]

The parameters under interest include the mean growth rate \(\mu\), and the coefficients of the two ARMA process, \(\{\Phi_{p_1}(L), \Theta_{q_1}(L), \Phi_{p_2}(L), \Theta_{q_2}(L), \sigma_\eta, \sigma_\varepsilon, \sigma_{\eta \varepsilon}\}\).
Writing the model (1) more compactly gives the ARIMA representation of $y_t$.

$$
\Phi_{p_1}(L)\Phi_{p_2}(L)\Delta y_t = \Phi_{p_1}(1)\Phi_{p_2}(1)\mu + \Phi_{p_2}(L)\Theta_{q_2}(L)\eta_t + (1 - L)\Phi_{p_1}(L)\Theta_{q_1}(L)\varepsilon_t. \quad (2)
$$

This expression implies we can recover the parameters of the UC model by estimating the growth rate of GDP as a ARIMA process. Here we follow the strategy of Morley, et al. (2003) to estimate GDP as an ARIMA(2,1,2) process

$$
(1 - \phi_1 L - \phi_2 L^2)\Delta y_t = (1 - \phi_1 - \phi_2)\mu^* + (1 + \theta_1 L + \theta_2 L^2)u_t. \quad (3)
$$

Table 1 reports the estimated results. Note that $\gamma_j$ are the $j$-th order autocovariance of MA part of ARIMA process, and $\mu^*$, $\sigma_u$ and $\gamma_j$ are in percentages. The data used is U.S. quarterly real GDP from 1948:Q1 to 2008:Q1.

The absence of real roots in AR part indicates that the polynomial $(1 - \phi_1 L - \phi_2 L^2)$ cannot be factored further. This fact induces us to determine the form of $\Phi_{p_1}(L)$ and $\Phi_{p_2}(L)$ only in two alternative ways: $\Phi_{p_1}(L) = 1$, $\Phi_{p_2}(L) = (1 - \phi_1 L - \phi_2 L^2)$ or $\Phi_{p_1}(L) = \Phi_{p_2}(L) = (1 - \phi_1 L - \phi_2 L^2)$.

 Obviously, the first case is just the specification in Morley et al (2003), in which permanent component $g_t$ is a random walk. And the second case is the one we want to discuss, in which $g_t$ is

---

1. Oh et al. (2008) also recommend this specification. They find that ARIMA (2,1,2) is preferred by the AIC and ARIMA (1,1,0) is preferred by the BIC. However, the latter specification is not able to capture the periodical behavior of output due to its oversimplified structure.

2. The setting $\Phi_{p_1}(L) = (1 - \phi_1 L - \phi_2 L^2)$, $\Phi_{p_2}(L) = 1$ is infeasible, since this will make the order of MA part of $\Delta y_t$ (the RHS of (2)) exceed 2.
a general ARIMA(2,1,2) process.

Once \( \Phi_p(L) \) and \( \Phi_p(L) \) are determined, we can find the form of MA polynomials \( \Theta_q(L) \) and \( \Theta_q(L) \). In particular, to ensure the RHS of (2) be a MA(2) process, \( \Theta_q(L) \) and \( \Theta_q(L) \) can at most take the form of \((1 + \psi_1 L + \psi_2 L^2)\) and \((1 + \theta L)\), respectively. Now the parameters of interest are \( \{\psi_1, \psi_2, \theta, \sigma_\eta, \sigma_\varepsilon, \sigma_{\eta \varepsilon}\}^3 \), and the representation (2) is reduced to

\[
(1 - \phi_1 L - \phi_2 L^2) \Delta y_t = (1 - \phi_1 - \phi_2)\mu + (1 + \psi_1 L + \psi_2 L^2) \eta_t + (1 - L)(1 + \theta L) \varepsilon_t \tag{4}
\]

Remember that we have estimated the autocovariances of the RHS of last equation from the data, see \( \{\gamma_0, \gamma_1, \gamma_2\} \) in Table 1. Equate these moments to their counterparts in (4) and after some algebra, we get three equations for six parameters \( \{\psi_1, \psi_2, \theta, \sigma_\eta, \sigma_\varepsilon, \sigma_{\eta \varepsilon}\} : \\

\[
\begin{align*}
\sigma_\eta^2 &= \frac{\gamma_0 + 2\gamma_1 + 2\gamma_2}{(1 + \psi_1 + \psi_2)^2}, \\
\sigma_\varepsilon^2 &= \frac{-2(1 + \psi_1 \theta - \psi_1 - \psi_2 \theta)(\gamma_2 - \psi_2 \sigma_\eta^2) - (\theta - \psi_1)(\gamma_0 - (1 + \psi_1^2 + \psi_2^2)\sigma_\eta^2)}{2\theta(1 + \psi_1 \theta - \psi_1 - \psi_2 \theta) - 2(\theta - \psi_2)(1 - \theta + \theta^2)}, \\
\sigma_{\eta \varepsilon}^2 &= \frac{\theta[\gamma_0 - (1 + \psi_1^2 + \psi_2^2)\sigma_\eta^2] + 2(1 - \theta + \theta^2)(\gamma_2 - \psi_2 \sigma_\eta^2)}{2\theta(1 + \psi_1 \theta - \psi_1 - \psi_2 \theta) - 2(\theta - \psi_2)(1 - \theta + \theta^2)}. 
\end{align*}
\tag{5}
\]

The MA(2) process has only three autovariances, but we have six unknown parameters. This implies our UC model is unidentified.

In order to obtain two structural (or orthogonal) shocks, we need to set \( \sigma_{\eta \varepsilon} \) to be zero. The reader may ask whether this restriction is feasible\(^4\), since in Morley et al. (2003), when permanent component is a random walk, two innovations are always highly negative correlated. In fact, as long as the long-run effect (see the last row in Table 1) in the ARIMA representation of GDP is larger than 1, the orthogonality restriction in our modified UC model is always feasible. A formal mathematical proof can be found in the Corollary 1 of Nagukara (2008).

To learn the relationships of the unknown parameters, one method is solve three of them as functions of the other two. Unfortunately, the system (5) is nonlinear and fairly complicated, we cannot solve it in a closed form. So we resort to numerical method. Figure 1 below plots \( \{\psi_1, \sigma_\eta, \sigma_\varepsilon\} \) as functions of \( \psi_2 \) and \( \theta \). In addition, to ensure \( \Delta g_t \) be invertible and \( \sigma_\varepsilon^2 \) always positive, \( \psi_2 \) must be in the range around 0.6 to 1.

One thing worth noting in Figure 1 is that \( \{\psi_1, \sigma_\eta, \sigma_\varepsilon\} \) are monotonic functions of \( \psi_2 \), and the monotonicity does not change for different \( \theta \). In particular, given any value of \( \theta, \psi_1 \) and \( \sigma_\eta \)

\(^3\)The mean growth rate \( \mu \) is just the same as that in ARIMA representation.

\(^4\)Here, "feasible" means the equation system (5) always has solution when \( \sigma_{\eta \varepsilon} = 0 \).
are strictly deceasing in $\psi_2$, and $\sigma_\varepsilon$ is strictly increasing in $\psi_2$. Therefore, the standard deviation of transitory shock $\varepsilon_t$ reaches its maximum when $\psi_2$ approaches to 1. Since $\sigma_\varepsilon$ is a continuous function of $\psi_2$ and $\theta$, without loss of generality, we fix $\psi_2 = 1$ for different $\theta$ to find the largest transitory component (in terms of variance) in our modified UC model. Figure 2 plots $\sigma_\varepsilon$ against $\theta$, when $\psi_2 = 1$. The figure shows that $\sigma_\varepsilon$ reaches its unique maximum of 0.4442 at $\theta = -0.63$.

Figure 1: The relationship between $\{\psi_1, \sigma_\eta, \sigma_\varepsilon\}$ and $\{\psi_2, \theta\}$

Figure 2: The maximum of $\sigma_\varepsilon$ for different $\theta$ in (-1,1)

The above analysis implies that our UC model can be just identified, if the transitory and permanent components are forced to be orthogonal and the volatility of transitory component reaches its upper bound. In the next section, we will study the dynamic features of the two components under the above identification method and compare the results with those obtained by using the Blanchard-Quah (BQ) (1989) decomposition.
3. Dynamics

The largest possible variance of the transitory component \( \{c_t\} \) has standard deviation 0.4442 when setting \( \theta = -0.63 \) and \( \psi_2 = 1 \). The remaining parameters \( \psi_1 \) and \( \sigma_\eta \) can be solved directly from the equation system (5). In particular, we have \( \psi_1 = -1.2612 \) and \( \sigma_\eta = 0.6059. \) Since both BQ (1989)\(^6\) and our UC model implement orthogonal decomposition with a general unit-root permanent component, we can use impulse responses and variance decomposition to compare our results with theirs. To ensure consistency (i.e., GDP in the bivariate BQ decomposition must also follow a ARIMA(2,1,2) process), we estimate a 2-variable VAR system with GDP growth and unemployment rate as a vector ARMA(1,1) process. We use RATS 7.0 to conduct the estimation.

Figure 3 plots the impulse responses of GDP to a one-standard-deviation permanent and transitory shock respectively.\(^7\) In particular, under the permanent shock \( \eta_t \) (the left graph), output in our UC model has a larger and periodic response compared with that obtained by the BQ method. The maximum response climbs to the peak after six quarters. The long run effect of the permanent shock is also significantly larger (about 1.1), while under the BQ decomposition this value is only around 0.6. Under the transitory shock \( \varepsilon_t \) (the right graph), output movement in our model dies out quickly, while under the BQ decomposition the response is much larger and more persistent.

Figure 3: Responses of GDP to different shocks

To see the relative importance of two shocks to the GDP volatility, Table 2 reports the variance decomposition, i.e., the proportion of fluctuations due to transitory shock \( \varepsilon_t \) in different forecasting

\(^5\)The parameters \( \{\sigma_c, \sigma_\eta, \psi_1\} \) are statistically significant, we calculate their \( t \) statistics by Bootstrapping method, but not report here.

\(^6\)In their paper, BQ decompose GDP based on a structural bivariate VAR system of (\( \Delta GDP, Unemployment \) rate). They just identify the model by imposing a long run restriction on transitory component.

\(^7\)The dashed lines are 95% bootstrapped confidence interval computed (200 replications) by Hall’s percentile interval.

Note: The numbers in Column 2 and 3 are percentage of forecasting error due to transitory shock. The numbers in parentheses are 95% confidence intervals.

Even through the error bands of the BQ decomposition are large, contribution of transitory shocks to GDP are significant lower in our model even compared with the lower bound of the BQ decomposition (except for the impact period). That is, our model attributes most fluctuations of output to permanent shock; the transitory component is less important.

To see what may have caused these discrepancies in the two different approaches, we compare the data generating processes of output implied by these two estimations. Since we estimate the bivariate system of BQ decomposition as a VARMA(1,1) process, the growth rate of GDP can be recovered as an ARMA(2,2) process. Table below (in comparison with Table 1) lists the implied parameters under the VARMA (asterisk indicates the value is significantly different from the univariate ARMA(2,2) used in the UC model). Clearly, these different values implied by the VARMA (1,1) and the univariate ARMA (2,2) induce a much smaller long run effect. This explains why the permanent shock in the BQ decomposition has smaller long run effect than what we obtain in the UC model.

Table 3: ARIMA(2,1,2) implied by VARMA(1,1)

</tr>
</tbody>
</table>

In fact, this point can be easily seen from a spectrum perspective: the spectrum of growth rate of GDP shares the same value with growth rate of permanent component at zero frequency, and this value is just the squared long-run effect multiplying the variance of innovation in ARIMA process.
4. Conclusions

This note re-examines the UC method of decomposition of GDP by relaxing the random-walk assumption made in the existing UC literature. Based on this generalization, we are able to decompose GDP into two orthogonal components: permanent and transitory. The orthogonality allows us to conduct impulse response analysis and variance decompositions. We find that the permanent component explains the bulk of GDP fluctuations, in sharp contrast to the conclusion reached by Blanchard and Quah (1989).
