Was there a "Greenspan conundrum" in the Euro area ?*

Gildas Lamé[†]

June 11, 2013

Abstract

This paper implements an affine term structure model that accommodates "unspanned" macro risks for the Euro area, i.e. distinct from yield-curve risks. I use a Near-Cointegrated VAR-like approach to obtain a better estimation of the historical dynamics of the pricing factors, thus providing more accurate estimates of the term premium incorporated into the Eurozone's sovereign yield curve. I then look for notable episodes of the monetary cycle where long yields display a puzzling behavior vis-à-vis the short rate and its expected average path in contrast with the Expectation Hypothesis. The Euro-area bond market appears to have gone through its own "Greenspan conundrum" between January 1999 and August 2008. The term premium substantially contributed to these odd phenomena.

1 Introduction

In February 2005 during a speech before Congress, former Federal Reserve chairman Alan Greenspan noted that the 10Y treasury yield failed to increase significantly so far despite the 150-bp increase in the federal funds rate. This behavior was puzzling under the prevailing term structure theory called the "Expectation Hypothesis" as long rates should have also increased mechanically. While Greenspan mentioned several possible explanations for the phenomenon such as the global savings glut, the origin of this "conundrum" was left without any relevant answers at that moment. In a later monetary policy testimony in July 2005, Greenspan emphasized that yields can be divided into two components : the first one reflecting short-rate expectations and a second term a risk compensation. He suggested the prominent role of this second component in the relatively stable levels of long-term interest rates. Previous studies suggest this risk premium in the US is time-varying and substantial, thus complicating the transmission of monetary policy as it blurs the relationship between short-term interest rates controlled by central bankers and the long-term ones.

As the sovereign yield curve matters for businesses and households through the interest-rate channel and putting aside the current problems due to the sovereign debt crisis, one central question naturally follows : in parallel with the American conundrum, were there any periods before the crisis when long rates didn't seem to be responsive to rate hikes in the Eurozone ? That is, was there also a "Greenspan conundrum" in the Euro area ? If the answer is affirmative, was the term premium behind it ? These questions are deemed essential if one assumes the Expectation Hypothesis should hold. Assessing the relative role of the term premium in shaping long-term interest rates will also help policymakers in their evaluation of the transmission channel between the policy rate and long-term yields. Affine term structure models represent one way to answer this question. Naturally, macroeconomic factors ought to play a significant role in the determination of short-rate expectations and risk premia. Therefore, a dynamic term structure model which includes not only the standard "level", "slope" and "curvature" factors but also macroeconomic factors is welcomed. Furthermore, Eurozone data favor a model which accommodates unspanned macro risks, i.e. risks that impact bond investment decisions separately from information about the shape of the yield curve.

In this paper, I implement a simple and parsimonious dynamic term structure model initially developed by Joslin et al. (2010)[10] based on a vector of pricing factors which includes the first three principal components of yields and two macroeconomic factors (an economic activity indicator and inflation) for the Euro area. Their model has the interesting feature of accommodating unspanned macro risks, feature that should be taken into account in a model for the Euro area as economic activity and inflation are not "spanned" by the yield curve. The usual estimation of such affine term structure model is done with a two-step procedure which consists in a first phase in the estimation of the historical dynamics of the pricing factors and then the risk-neutral dynamics while taking advantage of the cross-section of yields. I improve the first step by using an estimation method inspired by Jardet et al. (2012)[9]. By taking into account unit-root constraints, cointegration relationships among state variables and by minimizing the long-term forecast errors of the state

variables, the implemented methodology provides better estimates of long-term expectations of the short rate and thus more accurate long-horizon term premium. Given the mysterious nature of the premium's determinants, my estimate should be viewed as capturing any effects that might impact the price of Euro-area riskless sovereign bonds other than expected future monetary policy. Focusing on the 5Y maturity for the Eurozone, I find that the 5Y yield term premium has been hovering around 1% and represent on average over the period 21% of the 5Y bond yield. All in all, under the framework of the Expectation Hypothesis, the Euro area also went through its own "Greenspan conundrum" with the 5Y yield behaving counter-intuitively. I distinguish three notable "conundra" episodes from 1999 to 2008. Similar to past US analyses, two of them took place during the monetary policy tightenings decided by the ECB. The third one deserves particular attention as it took place at the same time as the US bond market's conundrum between June 2004 and December 2005. The estimated affine term structure model uncovers the dominant role of the term premium in these "euro-conundra".

2 Related literature

Several papers developed yield curve models with no macroeconomic component such as the popular factor models of Duffie and Kan (1996)[6] or Dai and Singleton (2000)[5], in which the set of yields is explained by a few latent factors. Joslin et al. (2011)[11] among others develop an affine term structure model with only observable factors. A number of papers model the joint dynamics of the macroeconomy and interest rates such as Ang and Piazzesi (2003)[1]. In addition to three latent factors, they also include two macroeconomic variables extracted from the PCA on a set of inflation-related measures and on another set reflecting real activity. But the majority of these macro-finance models make the implicit assumption that macroeconomic variables are actually risk factors determined by yields. On the contrary, Joslin et al. (2010)[10] introduce affine term structure models with observable yields and macro factors that accommodate unspanned macro risks.

Another important issue being dealt with in the literature is the high persistence displayed by interest rates. With relatively short samples (Euro area for example), estimating correctly the historical dynamics is not straightforward and often leads to errors. Modeling it with a standard VAR would often lead to flat long-term expectations of the short rate. Kim and Orphanides (2012)[12] manage to circumvent that problem by including survey data on long-term rates expectations so that their model-implied expectations match those of the market. Another possibility is to estimate the dynamics by properly taking into account their persistence like Jardet et al. (2012)[9]. They make use of averaging estimators which combine estimates resulting from a standard unconstrained VAR and those obtained with a constrained one which takes into account cointegration relationships.

The "Greenspan conundrum" in the US has been extensively studied by the literature and many contributions focused on the term premium which estimation has been very challenging. Several papers, such as Bernanke et al. (2004)[3], Cochrane and Piazzesi (2005)[4], Kim and Wright (2005)[13] attempt to obtain a precise estimation of the US term premium. However, the structural deter-

minants of the term premium are still mysterious, though the search for these fundamental-based macroeconomic factors remains a work in progress. Piazzesi and Scheinder (2007)[16] or Bansal and Shaliastovich (2013)[2] develop utility-based models for the term structure of interest rates. They both show that inflation underpins bond risk premium. On the empirical side, Wright (2011)[20] finds that inflation uncertainty is a significant determinant with a cross-country analysis.

As for the conundrum itself, Kim and Wright (2005)[13] find that a declining term premium was the key factor behind the puzzling behavior of long-term interest rates. Rudebusch and Al. (2006)[17] compare several term premium's estimates and noted the decreasing trend during the 2004-2005 period. As Kim and Wright (2005)[13] note, practioners often cite several possible factors responsible for the "Greenspan conundrum" in the US. Better-anchored inflation expectations with a reduction in macro volatility are one plausible explanation. Analysts also cite the increased foreign interest in US long-term bonds. Rudebusch et al. (2008)[18] underline the significant role of "out-of-model" variables during the conundrum such as the volatility of long-term treasury yields, foreign official purchase of Treasury bonds etc. Generally speaking, supply/demand adequation can be said to be the main cause of the conundrum. In contrast, Thornton (2012)[19] views the conundrum as evidence of the severed link between the short and long-term rates in the US. Assuming the term structure to be anchored by the long-term rate, which in turn depends on macroeconomic fundamentals such as productivity, is more relevant than the famous "Expectation Hypothesis". He suggests change in the use of the Federal Funds rate by the FED was behind the conundrum as the long-term rate still depends on fundamentals while the short rate is essentially impacted by monetary policy considerations.

3 A term structure model with macro factors

3.1 Term premium

Financial theory states that the term structure of interest rates is governed by what is usually called the "Expectation Hypothesis" (EH). According to this hypothesis, the expected return an investor expects from holding a long-term bond until maturity is the same as the expected return one gets when rolling over a series of short-term bonds. Equivalently, the long-term yield is equal to the average expected short-term yield. Unfortunately, with risk-averse investors, this hypothesis is unlikely to hold, given that a compensation may be required by them in order to hold such bond. The term premium refers exactly to this compensation for bearing the risk of variation in the riskless rate. In this paper, I will only consider the following term premium :

$$Yield\ premium : YTP_t^n = y_t^n - \frac{1}{n} \sum_{i=0}^{n-1} \mathbb{E}_t(r_{t+i}) = y_t^n - Exp_t^n \quad (1)$$

Here r_t denotes the short rate ie the one-period yield y_t^1 , y_t^n the yield of a n -period zero-coupon bond and $Exp_t^n = \frac{1}{n} \sum_{i=0}^{n-1} \mathbb{E}_t(r_{t+i})$, the expected average path of the short rate over the next n periods.

3.2 The general setup

Following Ang and Piazzesi's (2003)[1], I implement here a standard discrete-time affine term structure model which also incorporates unspanned macro risks as developed in Joslin et al. (2010)[10].

Let P_t be a N_1 -dimensional vector of pricing factors, M_t a N_2 -dimensional vector of macro factors ($N = N_1 + N_2$) and $Z_t = [P_t, M_t]$. Suppose the short rate satisfies the following equation :

$$r_t = \rho_0 + \rho_1 Z_t \quad (2)$$

The state factors Z_t follow a first order Gaussian VAR under the probability measure \mathbb{P} :

$$\Delta Z_t = K_{0Z}^{\mathbb{P}} + K_{1Z}^{\mathbb{P}} Z_{t-1} + \Sigma_Z \varepsilon_{Z_t}^{\mathbb{P}} \quad (3)$$

where $\varepsilon_{Z_t}^{\mathbb{P}} = \varepsilon_t \sim N(0, I_N)$ and Σ_Z is a non-singular $N \times N$ matrix ¹.

Under the assumption of complete markets and no arbitrage, there exists a risk-neutral probability measure that is equivalent to the physical measure. Under this measure, the state vectors follow an alternative law of motion :

$$\Delta Z_t = K_{0Z}^{\mathbb{Q}} + K_{1Z}^{\mathbb{Q}} Z_{t-1} + \Sigma_Z \varepsilon_{Z_t}^{\mathbb{Q}} \quad (4)$$

with $(K_{0Z}^{\mathbb{Q}}, K_{1Z}^{\mathbb{Q}})$ both linearly related to $(K_{0Z}^{\mathbb{P}}, K_{1Z}^{\mathbb{P}})$ by the market prices of risk. (see Appendix A for further details). Under the risk-neutral measure, states of the world in which investor's marginal utility is high are in fact overweighed compared to the situation in the physical world.

Within a risk-neutral pricing framework, the price of a zero-coupon bond can be written simply as :

$$p_t^n = \mathbb{E}_t^{\mathbb{Q}} \left[\exp \left(- \sum_{i=0}^n r_{t+i} \right) \right] \quad (5)$$

Bond prices are actually exponential affine functions of the state variables. More precisely, bond prices are given by :

$$p_t^n = \exp \left(\overline{A}_n + \overline{B}'_n Z_t \right) \quad (6)$$

where the coefficients \overline{A}_n is a scalar and \overline{B}'_n is a $N \times 1$ vector for a given maturity. The continuously-compounded bond yield y_t^n is then:

$$y_t^n = A_n + B'_n Z_t \quad (7)$$

with $A_n = -\overline{A}_n/n$ and $B_n = -\overline{B}_n/n$.

¹I choose in the paper to only consider a VAR(1)-based affine term structure model for parsimony. This setting makes the estimation of the model easier and faster.

3.3 A model with unspanned macro risks

In the present affine term structure model, I allow the yield curve to respond to macroeconomic shocks and vice-versa.

Given equation (7), both P_t and the macro factors determine the model-implied bond yields. Such models are said to contain "spanned macro risks" (see Joslin et al. (2010)[10] and Ludvigson & Ng (2009)[14] for example). With the bond yields as given, one would be able to solve for the factors using (7) and would conclude that M_t is "spanned" by bond yields². If this model correctly reflects reality, then projections of macro factors on the P_t should yield excellent adjusted R^2 , which is rarely the case with empirical data. Another problem with including macro factors is the subsequent decrease in pricing power. Absence of additional pricing power to the model is also possible. The three native yield-curve factors P_t are actually sufficient to replicate observed bond yields.

Everything above suggests excluding macro factors but the compensations required by investors for bearing real-interest risk does necessarily depend on macroeconomic conditions. Including "unspanned macro risks" is one simple solution to reconcile these two contradicting stances. Restrictions can be imposed such that yields have a zero loading on macro factors in equation (7). However, it does not mean yields cannot have any forecasting power on the macro variables and vice-versa.

Suppose the last N_2 elements of ρ_1 and the upper-right $N_1 \times N_2$ block in $K_{1Z}^{\mathbb{Q}}$ are set equal to 0. Then equation (2) and (4)³ can be reduced to

$$r_t = \rho_0 + \rho_{1P} P_t \quad (8)$$

$$\Delta P_t = K_{0P}^{\mathbb{Q}} + K_{1P}^{\mathbb{Q}} P_{t-1} + \Sigma_P \varepsilon_{P_t}^{\mathbb{Q}} \quad (9)$$

with ρ_{1P} and $K_{0P}^{\mathbb{Q}}$ two N_1 -dimensional vectors, $K_{1P}^{\mathbb{Q}}$ a $N_1 \times N_1$ matrix, $\Sigma_P \Sigma'_P$ the $N_1 \times N_1$ upper-left block of $\Sigma_Z \Sigma'_Z$ and $\varepsilon_{P_t}^{\mathbb{Q}} \sim N(0, I_{N_1})$.

Those restrictions also imply that the last N_2 elements of B_n are equal to 0. Thus, equation (7) is equivalent to

$$y_t^n = \widetilde{A}_n + \widetilde{B}_n' P_t \quad (10)$$

where \widetilde{A}_n and \widetilde{B}_n are deduced with recursive equations (see Appendix A).

In such framework, changes in the macro factors do not impact the current yield curve and they are not needed to fit the cross-section of bond yields at time t according to equation (10). With unspanned macro factors, only the risks associated with P_t are priced by the model. However, even if macro risks are not explicitly present in the risk-neutral dynamics, they still have a significant impact through the historical dynamics (3). Macro factors impact the average expected path Exp_t^n and the term premium YTP_t^n but both effects actually cancel out each other at each time t ⁴.

²The macro variables could be described through the following equation : $M_t = a_0 + a_1' P_t$

³In this paper, I will only model the risk-neutral dynamics without modeling the market prices of risk which would create a direct link between the historical and risk-neutral dynamics.

⁴Like JSP, I also suppose that the inclusion of spanned or unspanned macro factors in the affine term structure

4 The data

4.1 Yield data

I use data on monthly zero-coupon bond yields of maturities 6, 12, 24, 36, 60, 84 and 120 months from January 1999 to August 2008. The short-term rate used throughout the paper is the 1-month OIS rate rather than the 1-month Euribor in which non-negligible liquidity and credit risk premia are priced. Until September 2004, I use the German sovereign yield curve ⁵ as representative of the Euro area risk-free interest rates. From October 2004 to August 2008, zero-coupon bond yields provided by the ECB for the Eurozone AAA countries are used in this paper. All yield data are end-of-month. Some of the sovereign yields are plotted in figure 1.

According to Joslin et al. (2011)[11], P_t can be rotated to become principal components of bond yields. A PCA shows that the first three principal components of bond yields explain 99.9% of the cross-sectional variation. I choose to use the first $N_1 = 3$ PCs of bond yields ⁶, which are usually interpreted as the level, slope and curvature of the yield curve as the yield pricing factors P_t .

Figure 1: Eurozone historical zero-coupon bond yields for three different maturities.

Table 1 reports some descriptive statistics of the various bond yields used in the sample.

model is independent of the issue of bond yields' or macro factors' measurement errors.

⁵provided by the Bundesbank

⁶Like others in the literature, I rescale the principal components obtained from the PCA. we denote $l_{j,i}$ the loading on yield i in the construction of PC_j , the PCs have been rescaled so that: (1) $\sum_{i=1}^8 l_{1,i}/8 = 1$, (2) $l_{2,10Y} - l_{2,6M} = 1$ and (3) $l_{3,10Y} - 2l_{3,2Y} + l_{3,6M} = 1$. This way, the PCs are on a similar scale. All the variables I will be using take on values in $[-3\%, 8\%]$.

Figure 2: Historical series of the first three principal components of bond yields from 1999 to Aug 2008.

4.2 Macro variables

I use two macro variables in the model. The first one is the Economic Sentiment Indicator for the Euro area (rescaled)⁷, published every month by the European Commission, which is to capture real activity. The second one is the Euro-Area monthly year-on-year inflation (HICP, overall index). Figure 3 plots the two variables.

To assess the need for a model that accommodates "unspanned" macro risks, we can check how

⁷The ESI is issued following harmonized surveys by the European Commission for different sectors of the economy in the European Union. Industry (manufacturing), services, retail trade and construction sectors, as well as consumers contribute to the indicator. The raw indicator is rescaled so that the variable take on values in $[-2\%, 4\%]$

well the macro factors are explained by the PCs . With the present data sample, the projection of real activity on the first three PCs of yields gives an adjusted R^2 of 55% and the projection of inflation 15%. Thus almost 45% of the variation in activity and 85% of inflation do not stem from the yields' PCs .

Projections of changes in activity and inflation onto changes in the three PCs give even smaller adjusted R^2 (21% and 1% respectively). All in all, accommodating unspanned macro risks in the Gaussian term structure model is welcomed.

5 Estimation

5.1 First approach

The methodology used for the estimation of the model closely follows Joslin et al. (2010)[10] but without the reparametrization detailed in Joslin et al. (2011)[11], which reduces the number of parameters to be estimated and allows for faster computation. Nevertheless, I choose to stick to a standard procedure which will be detailed below. The parameters to be estimated are included in the following equations under the risk-neutral measure :

$$r_t = \rho_{0P} + \rho_{1P}P_t \quad (11)$$

$$\Delta P_t = K_{0P}^{\mathbb{Q}} + K_{1P}^{\mathbb{Q}}P_{t-1} + \Sigma_P \varepsilon_{P_t}^{\mathbb{Q}} \quad (12)$$

And under the physical measure:

$$\Delta Z_t = K_{0Z}^{\mathbb{P}} + K_{1Z}^{\mathbb{P}}Z_{t-1} + \Sigma_Z \varepsilon_{Z_t}^{\mathbb{P}} \quad (13)$$

In the model, the Z_t are priced without errors ($Z_t = Z_{t,o}$) whereas the zero-coupon bond yields equal their model-implied counterparts plus mean zero, normally distributed errors. As Joslin et al. (2010)[10] relevantly remark, the absence of constraints linking the physical and risk-neutral measures allows me to separate the time-series properties of Z_t in the physical world from the cross-sectional constraints imposed by no-arbitrage. The conditional likelihood function (under \mathbb{P}) of the observed data ($y_{t,o}^n$) can be written as :

$$f(y_{t,o}^n | y_{t-1,o}^n, Z_{t-1}; \Theta) = f(y_{t,o}^n | Z_t; \rho_{0P}, \rho_{1P}, K_{0P}^{\mathbb{Q}}, K_{1P}^{\mathbb{Q}}, \Sigma_P) * f(Z_t | Z_{t-1}; K_{0Z}^{\mathbb{P}}, K_{1Z}^{\mathbb{P}}, \Sigma_Z) \quad (14)$$

As mentioned earlier, I suppose the yields on zero-coupon bonds $y_{t,o}^n$ equal their model-implied values $y_{t,m}^n = \widetilde{A}_n + \widetilde{B}_n' P_t$ plus mean zero, i.i.d. and normally distributed errors $\eta_t = y_{t,o}^n - y_{t,m}^n$, which entails :

$$f(y_{t,o}^n | Z_t; \rho_{0P}, \rho_{1P}, K_{0P}^{\mathbb{Q}}, K_{1P}^{\mathbb{Q}}, \Sigma_P) = (2\pi)^{-(J-N)/2} |\Sigma_\eta|^{-1} \times \exp\left(-\frac{1}{2} \|\Sigma_\eta^{-1} \times (\eta_t)\|^2\right) \quad (15)$$

Using the assumption under which Z_t is conditionally Gaussian, the second term can be expressed as :

$$f(Z_t | Z_{t-1}; K_{0Z}^{\mathbb{P}}, K_{1Z}^{\mathbb{P}}, \Sigma_Z) = (2\pi)^{-N/2} |\Sigma_Z|^{-1} \times \exp\left(-\frac{1}{2} \|\Sigma_Z^{-1} \times (Z_t - \mathbb{E}_{t-1}[Z_t])\|^2\right) \quad (16)$$

where $\mathbb{E}_{t-1}[Z_t] = K_{0Z}^{\mathbb{P}} + (I + K_{1Z}^{\mathbb{P}})Z_{t-1}$, J is the total number of yield maturities and where for a vector x , $\|x\|^2$ denotes the Euclidean norm squared $\sum x_i^2$.

The (conditional on $t = 0$) log-likelihood function is then the sum:

$$L = \sum_{t=1}^T \left[\log \left[f(y_{t,o}^n \mid Z_t; \rho_{0P}, \rho_{1P}, K_{0P}^Q, K_{1P}^Q, \Sigma_P) \right] + \log \left[f(Z_t \mid Z_{t-1}; K_{0Z}^P, K_{1Z}^P, \Sigma_Z) \right] \right] \quad (17)$$

Parameters in equation (3) can be estimated from time series without considering cross-sectional restrictions. If Z_t is priced perfectly by the model ($Z_{t,o} = Z_t$), Joslin et al. (2010)[10] prove that the ML estimates of (K_{0Z}^P, K_{1Z}^P) are actually given by the OLS estimation of the VAR(1) process Z_t ⁸ and are independent from (Σ_P, Σ_Z) . The remaining parameters of the model $(\rho_{0P}, \rho_{1P}, K_{0P}^Q, K_{1P}^Q, \Sigma_Z)$ are then estimated by maximum log-likelihood, assuming the observed bond yields are measured with an i.i.d Gaussian error (see Appendix C.2). I choose here not to take into account the internal-consistency constraint which requires model-implied yields to reproduce the *PCs*. Nevertheless, I check that the constraint actually holds *ex-post*⁹.

5.2 Near-cointegrated VAR (NCVAR)

Interest rates are well-known to be highly persistent and given the short range of data at my disposal on the Eurozone yield curve, bias can easily arise in the estimation of the historical dynamics of interest rates. Because of high persistence in the data, I face what the literature usually calls the "discontinuity problem", which is the huge difference between predictions (especially long-run forecasts of the short rate) based on unconstrained VAR models and those taking into account unit-roots and cointegration relationships.

The approach I use to solve these issues is largely drawn from Jardet et al. (2012)[9] and introduces "Near-Cointegrated VARs" (NCVAR) to get better estimations of long-run expectations, using averaging estimators. I call "CVAR" the model under the historical measure estimated under a VECM framework.

5.2.1 Unit roots and VECM model

Standard unit-root tests¹⁰ reveal that the first *PC*, which is a proxy for the level of the yield curve, is closer to a $I(1)$ process or at least very persistent, as well as PC_2 and *Inf*. Results are more mixed for PC_3 and the activity factor but given KPSS and ERS's superior power to the ADF test, PC_3 and *Act* are closer to stationarity. In the end, choosing a simple VAR to model the historical dynamics of Z_t will most likely lead to significant estimation bias, given the high persistence and potential cointegration relationships among the five state variables.

The historical dynamics of the factors which is described through equation (3) can be directly interpreted as a vector error correction model (VECM). I determine the rank r of matrix K_{1Z}^P with

⁸Actually, though additional lags should be considered in light of standard lag selection procedures, our sample is too limited in size. Nevertheless, if I consider a VAR(2) process for Z_t , the estimation shows most coefficients of Z_{t-2} are found to be not significantly different from 0. Thus, my VAR(1)-based model is still preferable.

⁹I find a RMSE of 1.7 bps which means the internal constraint holds *ex-post*.

¹⁰Appendix B

a Johansen cointegration tests using a trace and maximum eigenvalue test. r actually represents the number of cointegrating relationships among the state variables.

By choosing to write the VECM with equation (3), I actually make with the unrestricted constant term $K_{0Z}^{\mathbb{P}}$ the implicit hypothesis that there's a linear trend in Z_t or/and an intercept in the cointegrating component¹¹. Equation (3) can be rewritten as:

$$\Delta Z_t = \alpha (\beta' Z_{t-1} + c_0) + \Sigma_Z \varepsilon_{Z_t}^{\mathbb{P}} \quad (18)$$

or

$$\Delta Z_t = \alpha (\beta' Z_{t-1} + c_0) + c_1 + \Sigma_Z \varepsilon_{Z_t}^{\mathbb{P}} \quad (19)$$

with the decomposition $K_{0Z}^{\mathbb{P}} = \alpha c_0$ ($K_{0Z}^{\mathbb{P}} = \alpha c_0 + c_1$ respectively)¹². Under the restricted specification (18), the trace and eigenvalue tests both point to the same rank of cointegration. Both tests¹³ accept the presence of $r = 2$ cointegrating relations. Therefore, I can write $K_{1Z}^{\mathbb{P}} = \alpha \beta'$ where α is a (5×2) adjustment coefficient vector and β a (5×2) cointegrating vector¹⁴. The cointegration analysis was based on the model with a restricted constant so I still have to test the hypothesis $H_0 : K_{0Z}^{\mathbb{P}} = \alpha c_0$ against its alternative $H_a : K_{0Z}^{\mathbb{P}} = \alpha c_0 + c_1$ using a $\chi^2(3)$ -distributed likelihood ratio statistic (see Johansen (1995)) to confirm that specification (18) is the most appropriate one. The test confirms specification (18) and therefore tells us that there's no drift in the common trend¹⁵.

5.2.2 Averaging estimators

Averaging estimators were first proposed by Hansen (2010)[8]. The idea consists in combining two different kinds of estimators. Firstly, I estimate the parameter θ_{UNC} of the unconstrained VAR with one lag representing the historical dynamics of the factors by OLS. In a second step, I proceed with the estimation of a one-lag VECM of the state variables (therefore imposing unit-root constraints), which gives the parameter vector θ_{CON} . The averaging estimator specifying the Near-cointegrated VAR is then defined as :

¹¹Critical values of the Johansen test actually depend on the assumptions made concerning the cointegrating relations and the VECM which are :

- absence or presence of an intercept/trend in the cointegrating relations
- absence or presence of an intercept in the VECM (which is equivalent to a linear trend in the data. I choose to neglect quadratic trends).

¹²Actually, though additional lags should be considered in light of standard lag selection procedures, our sample is too limited in size. Nevertheless, if I consider a VECM for Z_t that also includes ΔZ_{t-2} , the estimation shows most coefficients of this term are found to be not significantly different from 0. Thus, my simple VECM is still preferable.

¹³See Appendix B

¹⁴Estimates of the different VECM parameters are provided in Appendix C.3.

¹⁵The likelihood ratio statistic is $LR = -T \sum_{j=3}^5 \log \left[\frac{(1 - \tilde{\lambda}_j)}{(1 - \lambda_j)} \right]$ where $(\lambda_j, \tilde{\lambda}_j)$ are the smallest eigenvalues associated to the maximum likelihood estimation of the unrestricted and restricted model respectively. I find $LR = 0.830$ which is lower than $\chi_{0.01}^2(3) = 11.35$

$$\theta_{NCVAR} = \theta_{NCVAR}(\lambda) = \lambda\theta_{UNC} + (1 - \lambda)\theta_{CON} \quad (20)$$

with $\lambda \in [0, 1]$ a parameter used to minimize a chosen criterion.

Given that the short rate will depend on the yields' PC s as stated in equation (8), I choose to focus on minimizing the forecast error (RMSFE) when predicting the PC s. As the objective is to provide a more precise estimation of the term premium, I could have actually minimized the error in forecasting the short-rate or Exp_t^n , given the definition of YTP_t^n in the paper. Jardet et al. (2012)[9] base their criterion on $\mathbb{E}_t^{\mathbb{Q}}[\exp(-(r_t + \dots + r_{t+h-1}))]$, thus having at disposal more points for the computation of the criterion. Both alternative approaches would have been more relevant but computationally more intensive in the present framework as λ , ρ_0 , ρ_1 and the parameters governing the historical/neutral dynamics of the state variables would have to be estimated simultaneously. So the present approach can benefit from the two-step estimation speed.

So for a forecast horizon h , the parameter $\lambda(h)$ is selected through the following minimization program :

$$\lambda^*(h) = \arg \min_{\lambda \in [0,1]} \sum_i \left[\sum_t \left(P_{i,t+h} - \mathbb{E}_t^{implied} [P_{i,t+h}] \right)^2 \right] \quad (21)$$

where $P_{i,t+h}$ is the observed realization of the PC_i for each date t and horizon h whereas $\mathbb{E}_t^{implied} [P_{i,t+h}]$ is the model-implied prediction of the PC_i . The criterion is just (up to a factor) the standard $TMSFE$ (Trace Mean Square Forecast Error).

Like a conventional out-of-sample forecasting exercise, I first estimate θ_{UNC} and θ_{CON} over the period 1999M1-2002M08¹⁶ and compute \hat{P}_{t+h} with $t = 2002M08$. For each later date t , I re-estimate θ_{UNC} and θ_{CON} over the expanded window and compute the model-implied forecast value of the PC s. This methodology replicates the typical behavior of an investor that incorporates new information over time. The out-of-sample forecasts are performed for $t \in [2002M09, 2008M08 - h]$.

In the end, as I'm interested in long-term risk premium, h is set equal to 60 months given the limited time length of the data and the optimization yields $\lambda = 0.3042$ with the Trace Root Mean Square Forecast Error (TRMSFE) being equal to 82 bps¹⁷, while for the VAR-based model $TRMSFE_{VAR} = 109$ bps and $TRMSFE_{CVAR} = 158$ bps for the CVAR-based one. This estimated value for λ implies θ_{NCVAR} is something closer to θ_{CON} than the VAR-based estimator (see Appendix C).

¹⁶I am clearly aware that the initial window is very narrow for an estimation of the historical dynamics but the relative short existence of the Eurozone leaves me with no other choice than using this short time span so that I can at least consider 5-year-ahead expectations of the PC s for the estimation strategy.

¹⁷The estimate of λ stays robust after slight changes to the initial time window (see Appendix for details).

6 Results

6.1 Parameters estimates

$(\rho_0, \rho_{1P}, K_{0P}^{\mathbb{Q}}, K_{1P}^{\mathbb{Q}}, K_{0Z}^{\mathbb{P}}, K_{1Z}^{\mathbb{Q}}, \Sigma_Z)$ ¹⁸ are initiated at the values obtained from the estimations of the associated standard VARs. Maximization of the log-likelihood and computation of the asymptotic standard errors (for the short-rate and risk-neutral parameters) are performed using a quasi-Newton algorithm as available in the Matlab software. Estimates for $(\rho_0, \rho_{1P}, K_{0P}^{\mathbb{Q}}, K_{1P}^{\mathbb{Q}})$ are highly significant because the estimation takes advantage from the large cross-sectional information on yields. In the end, the root mean square fitting error of yields is extremely low (around 1 bps), indicating that the first three *PCs* are able to account for almost all cross-sectional variation in yields thus proving that the specification of the \mathbb{Q} -dynamics of bond yields reflected in equation (4) and (10) is appropriate for Eurozone data. Observed and model-implied yields almost coincide. For instance, the difference between the observed and model-implied 5Y bond yield never exceeds 7 bps.

6.2 Estimation of the term premium

I attempt now to provide an estimate of the Eurozone term premium for the 5Y horizon as the averaging estimator was optimally chosen for this maturity¹⁹. Figure 4 first compares different estimates for the model-implied 5-year expected path of the short rate $Exp_t^{5Y} = \frac{1}{60} \sum_{i=0}^{60-1} \mathbb{E}_t(r_{t+i})$. As mentioned earlier, using a simple VAR-based term structure model would lead to a rather flat 5Y average expected short rate path while the one based on the CVAR model is much more volatile.

Figure 5 shows the 5Y term premium obtained with the model based on a VAR, CVAR and NVCAR processes. The figure typically illustrates once again the differences between the three methodologies with the VAR-based premium being much more volatile than the others for instance.

On average over the whole sample, the 5Y term premium in the model is estimated to represent 21% of the 5Y yield. It has therefore the potential to disturb the conduct of monetary policy in the Euro area.

7 Was there a bond yield conundrum in the Euro area ?

7.1 A first look

Under the assumption of the Expectation Hypothesis, long rates should be responsive to any changes in the short rate and its expected average path. What triggered the debate around the Greenspan conundrum was the muted response of long rates after the successive rate hikes decided by the FED between 2004 and 2006. Thus, in this parallel analysis, I check whether or not the Euro area also experienced the same thing during its monetary tightening episodes. Figure 6 shows how the 5Y rate

¹⁸Tables in Appendix C.4 give the estimated parameters of the term structure model based on the previously described NVCAR method

¹⁹Past US studies focused on the 10-year maturity. Unfortunately, due to limitations on the data, I can only consider the 5-year horizon.

Figure 4: Expected average path of the short rate over a 5-year horizon estimated with the VAR-based (blue dashed line), the NCVAR-based (red dash-dotted line) and the CVAR-based models (green dotted-line).

Figure 5: 5-year yield term premium estimated with the VAR-based (blue dashed line), the NCVAR-based (red dash-dotted line) and the CVAR-based models (green dotted-line).

evolved throughout the sample's period compared with its two components (Exp_t^{5Y} and YTP_t^{5Y}) and r_t as estimated with the NCVAR model. At first sight, during the first episode of tightening, from November 1999 to March 2000, the short-term interest rate rose while the 5Y interest rate increased somewhat to around 5.20% with a stagnant Exp_t^{5Y} and a volatile YTP_t^{5Y} in the background.

What happened during the second episode is slightly different. A first phase can be distinguished with both yield components moving hand in hand in the same direction following the tightening. The second phase (June 2007 - January 2008) witnesses another puzzling phenomenon : the short rate is stable while the model-implied 5Y yield falls from 4.41% to 3.60%. The expectation component's puzzling behavior and its subsequent drop exceeded the term premium's growth which was not high enough to compensate for the fall of the former.

Apart from these periods discussed above from which a parallel has been drawn with past analyses on the US bond market, figure 6 reveals an intriguing event. From June 2004 to December 2005, while the US bond market was experiencing its "Greenspan conundrum", the Euro area was also going through its own "euro-conundrum" simultaneously. The short rate was stable during that period but the 5Y bond yield fell dramatically from 3.70% to 2.94%. Turning to the sub-components, the term premium was apparently the major contributor to this significant fall.

Figure 6: Evolution of the model-implied short rate (solid line), y_t^{5Y} (model-implied, dotted line), Exp_t^{5Y} (model-implied, solid line with circle markers) and YTP_t^{5Y} (model-implied, solid line with star markers) over the Eurozone's previous monetary tightening episodes (shaded in grey).

Under the framework of the EH and mirroring past US analyses, we saw that the Euro area experienced at least three notable phases of puzzling behaviors which we can dub "euro-conundra" : two of them displaying odd responses from bond yields after rate hikes in a similar fashion to the US

experience and a third one which took place simultaneously with the Greenspan conundrum. In all these episodes, the model's term premium apparently played a significant role, which I'll properly disentangle below.

7.2 Contribution analysis

Figure 7 plots the contributions of both the expectation (Exp_t^{5Y}) and the term premium component (YTP_t^n) of the 5Y bond yield during the first phase we described earlier. The figure confirms the dominant contribution of the 5Y term premium at first to the puzzling behavior of the associated bond yield which did not actually follow the average expected path of the short rate. Similar to what was found by the literature in the US, these movements of the 5Y yield we witnessed at the beginning of the monetary tightening was primarily driven by the term premium according to the model. As our estimate of the term premium is supposed to capture any effect that can impact sovereign bonds' prices, it is difficult to attribute one precise reason for this significant contribution of the risk premium. At least, given the stability of the average expected path of the short rate, the expected monetary policy effect must have been entirely captured instead by the term premium.

Figure 7: Contribution of Exp_t^{5Y} (in blue, left bar) and of YTP_t^{5Y} (in red, right bar) to the evolution of the 5-year bond yield (black dashed line) from November 1999 to March 2000.

Turning to the second tightening episode in Euro-area history, figure 8 plots again the contributions of both components associated to the 5Y bond yield. As suspected earlier, the fall of the long rate is actually due to investors' long-term expectations of the path of r_t . This tightening actually

stands out as the financial crisis began to slowly spread to the Eurozone. Investors believed the ECB could not hold for long their strong tightening monetary stance. Thus, it seems they changed their long-term expectations of the short rate's path in the future and already expected for a more accommodative policy from the ECB.

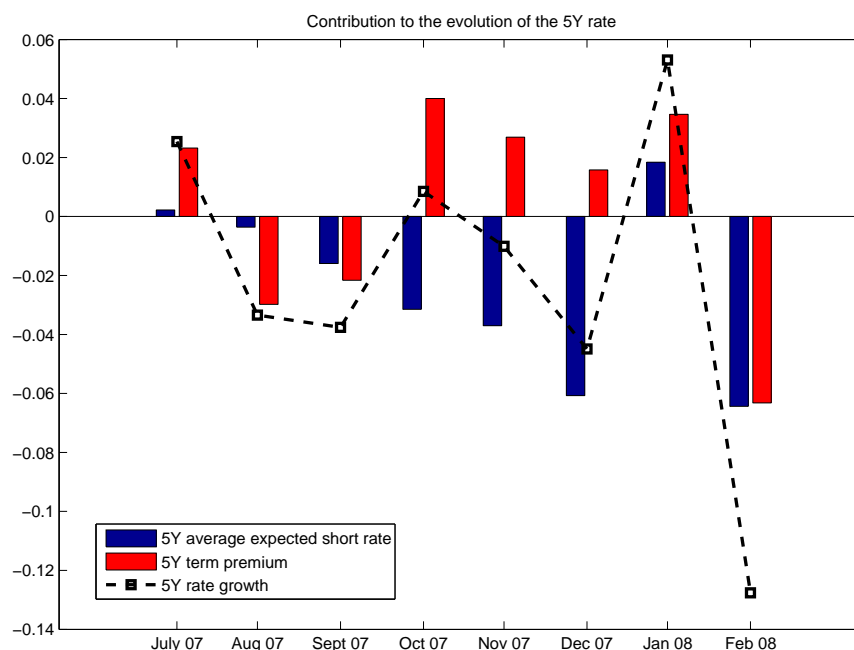

Figure 8: Contribution of Exp_t^{5Y} (in blue, left bar) and of YTP_t^{5Y} (in red, right bar) to the evolution of the 5-year bond yield (black dashed line) from June 2007 to January 2008.

The most interesting period in the Euro-area bond market is probably the one when the "Greenspan conundrum" actually took place at the same time in the US bond market. In figure 9, the orientation and length of the red bars show the significant impact of the 5Y term premium on the dramatic fall of the associated bond yield during that period even though the monetary policy rate was flat all that time. Again, given the large scope of effects captured by our term premium estimate, it is difficult to uncover the true factors that caused this conundrum at the same time as the American one. Therefore, it is probable that problems in the adequation between the supply and demand of sovereign bonds (due to several structural factors as mentioned in Kim and Wright (2005)[13]) also drove the term premium downward in the European bond market.

From the perspective of monetary policy, under the standard EH framework, the only way for the central bank to control long-term yields is by influencing market expectations of future monetary policy. The results presented here show that long bond yields don't always mechanically follow the short rate and its expected average path. However, under the extended framework of the EH, this paper finds that long-term risk-free yields in the Euro area are buffered by a substantial and time-varying term premium. Thus the central bank not only has to guide market expectations of its

future policy but it also has to take measures to alter this risk premium. Large-scale asset purchases are deemed to have significant effects from that point (see Gurkaynak and Wright (2012)[7] for a brief discussion on that matter).

Figure 9: Contribution of Exp_t^{5Y} (in blue, left bar) and of YTP_t^{5Y} (in red, right bar) to the evolution of the 5-year bond yield (black dashed line) from June 2004 to December 2005.

8 Conclusion

Central banks attempt to influence the movements of the sovereign yield curve. Unfortunately, the task is not without difficulties. The Expectation Hypothesis emphasizes the decisive role of short rate expectations in determining long-term interest rates. But deviations from the hypothesis primarily stem from investors' risk aversion, who then demand a risk premium.

In this paper, I estimate an arbitrage-free Gaussian term structure model for the Euro area which allows for macro risks to be priced distinctly from the yield curve. Indeed, the state factors of the model include macroeconomic variables which are not entirely spanned by bond yields. I also adopt a relevant estimation approach which yields better term premium estimates than a conventional unconstrained VAR model by using averaging estimators. The estimated term structure is consistent with the Euro area, as unspanned macro risks are taken into account in line with the observed data. Moreover, the econometric methodology used provides more accurate estimates of long-horizon term premium.

In parallel with past studies on the US bond market, the present analysis shows that the Eurozone

went through its own "Greenspan conundra". In contrast with what would have been predicted with the Expectation Hypothesis, long-term interest rates didn't follow the policy rate while the ECB tightened in 2000H1. In 2007-2008, just before the financial crisis, they fell unexpectedly. The most interesting feature is the simultaneous "Greenspan conundrum" in 2004-2005 in the US and Eurozone bond market. The estimated affine term structure model emphasizes the major contribution of the long term premium to the "conundra" in 2000 and 2004-2005, which is similar to the US case.

All in all, the term premium extracted from term structure models captures many effects and the true nature of this residual is still an open question, which does not help the central bank for the transmission of monetary policy. However, one can also consider that resorting to this risk premium to explain the deviations from the Expectation Hypothesis found in the data might be the proof of the shortcomings of this widespread term structure theory. As in Thornton (2012)[19], a term structure anchored on long rates might be a more relevant alternative to the prevailing Expectation Hypothesis.

A Appendix: The framework of the term structure model

A.1 Bond pricing

It can be shown that yields linearly depend on Z_t with $p_t^n = \exp(\overline{A}_n + \overline{B}'_n Z_t)$ (6) with $(\overline{A}_n, \overline{B}_n)$ both satisfying the following recursive equations :

$$\overline{A}_{n+1} = \overline{A}_n + \overline{B}'_n (K_{0Z}^{\mathbb{P}} - \Sigma_Z \lambda_0) + \frac{1}{2} \overline{B}'_n \Sigma_Z \Sigma'_Z \overline{B}_n - \rho_0 \quad (22)$$

$$\overline{B}_{n+1} = (I + K_{1Z}^{\mathbb{P}} - \Sigma_Z \lambda_1)' \overline{B}_n - \rho_1 \quad (23)$$

The initial conditions are $\overline{A}_1 = -\rho_0$ and $\overline{B}_1 = -\rho_1$. (λ_0, λ_1) are the market prices of risk.

When $\lambda_0 = \lambda_1 = 0$, investors are then supposed to be risk-neutral. In fact, risk-averse investors actually value any bonds the same way as risk-neutral investors do if the latter thought that the state vectors follow an alternative law of motion under a different probability measure \mathbb{Q} :

$$\Delta Z_t = K_{0Z}^{\mathbb{Q}} + K_{1Z}^{\mathbb{Q}} Z_{t-1} + \Sigma_Z \varepsilon_{Z_t}^{\mathbb{Q}} \quad (24)$$

where $K_{0Z}^{\mathbb{Q}} = K_{0Z}^{\mathbb{P}} - \Sigma_Z \lambda_0$ and $K_{1Z}^{\mathbb{Q}} = K_{1Z}^{\mathbb{P}} - \Sigma_Z \lambda_1$.

Equation (3) is commonly referred to the physical/historical risk representation and (4) as the risk-neutral representation of the law of motion for the state vector (\mathbb{P} and \mathbb{Q} respectively). Notice that both laws are identical to each other when $\lambda_0 = \lambda_1 = 0$, which is equivalent to the hypothesis of risk-neutral investors.

To estimate the model, one can either specify the set of parameters as $(\rho_0, \rho_1, K_{0Z}^{\mathbb{P}}, K_{1Z}^{\mathbb{P}}, \lambda_0, \lambda_1, \Sigma_Z)$ or in terms of $(\rho_0, \rho_1, K_{0Z}^{\mathbb{P}}, K_{1Z}^{\mathbb{P}}, K_{0Z}^{\mathbb{Q}}, K_{1Z}^{\mathbb{Q}}, \Sigma_Z)$. With the second parametrization, one needs to specify the factors' dynamics under the historical and risk-neutral measure in the model's assumptions. Following standard risk-neutral asset pricing, the price of any zero-coupon bond can then also be written as :

$$\begin{aligned} p_t^n &= \mathbb{E}_t^{\mathbb{Q}} \left[\exp \left(- \sum_{i=0}^n r_{t+i} \right) \right] \\ &= \exp \left(\overline{A}_n + \overline{B}'_n Z_t \right) \end{aligned} \quad (25)$$

with \overline{A}_n and \overline{B}_n following the usual recursive equations :

$$\overline{A}_{n+1} = \overline{A}_n + \overline{B}'_n K_{0Z}^{\mathbb{Q}} + \frac{1}{2} \overline{B}'_n \Sigma_Z \Sigma'_Z \overline{B}_n - \rho_0 \quad (26)$$

$$\overline{B}_{n+1} = (I + K_{1Z}^{\mathbb{Q}})' \overline{B}_n - \rho_1 \quad (27)$$

A.2 A model with unspanned macro factors

In the modified framework, the continuously-compounded bond yield is now related to the pricing factors through \widetilde{A}_n and \widetilde{B}_n which are obtained with the following recursive equations :

$$\overline{A_{n+1}} = \overline{A_n} + \overline{B'_n}(K_{0P}^Q) + \frac{1}{2}\overline{B'_n}\Sigma_P\Sigma'_P\overline{B_n} - \rho_0 \quad (28)$$

$$\overline{B_{n+1}} = (I + K_{1P}^Q)'\overline{B_n} - \rho_1 \quad (29)$$

with $\overline{A_1} = -\rho_0$, $\overline{B_1} = -\rho_1$, $\widetilde{A}_n = -\overline{A_n}/n$ and $\widetilde{B}_n = -\overline{B_n}/n$.
