# Was there a "Greenspan conundrum" in the Euro area ?\*

Gildas Lamé<sup>†</sup>

September 2013

## Abstract

This paper implements an affine term structure model that accommodates "unspanned" macro risks for the Euro area, i.e. distinct from yield-curve risks. I use an averaging-estimator approach to obtain a better estimation of the historical dynamics of the pricing factors, thus providing more accurate estimates of the term premium incorporated into the Eurozone's sovereign yield curve. I then look for episodes of the monetary cycle where long yields display a puzzling behavior vis-à-vis the short rate and its expected average path in contrast with the Expectation Hypothesis. The Euro-area bond market appears to have gone through its own "Greenspan conundrum" between January 1999 and August 2008. The term premium substantially contributed to these odd phenomena.

# 1 Introduction

In February 2005 during a speech before Congress, former Federal Reserve chairman Alan Greenspan noted that the 10-year treasury yield failed to increase significantly so far despite the 150-basis-point increase in the federal funds rate. This behavior was puzzling with respect to the prevailing term structure theory called the "Expectation Hypothesis" as long rates should have also increased mechanically. While Greenspan mentioned several possible explanations for the phenomenon such as the global savings glut, the origin of this "conundrum" was left without any precise answer at that moment. In a later monetary policy testimony in July 2005, Greenspan emphasized that yields can be divided into two components: the first one reflecting short-rate expectations and the second one a risk compensation. He suggested the prominent role of this second component in the relatively stable levels of long-term interest rates. Previous studies suggested that this risk premium in the US is time-varying and substantial, thus complicating the transmission of monetary policy as it blurs the relationship between short-term interest rates controlled by central bankers and the long-term ones.

As the sovereign yield curve matters for businesses and households in the Eurozone through the interests paid on long-term savings and putting aside the current problems due to the sovereign debt crisis, one central question naturally follows: in parallel with the American conundrum, were there any periods before the crisis when long rates did not seem to be responsive to changes in the policy rate in the Eurozone? That is, was there also a "Greenspan conundrum" in the Euro area? If the answer is positive, was the term premium behind this result? These questions are deemed essential if one assumes the Expectation Hypothesis should hold. Under this framework, long yields should be equal to the average expected path of the short rate. Assessing the relative role of the term premium in shaping long-term interest rates can also help policymakers in their evaluation of the transmission channel between the policy rate and long-term yields. Affine term structure models represent one way to answer this question. Naturally, macroeconomic factors ought to play a significant role in the determination of short-rate expectations and risk premia. Therefore, a dynamic term structure model which includes not only the standard "level", "slope" and "curvature" factors but also macroeconomic factors is welcomed.

In this paper, I implement a simple and parsimonious dynamic term structure model initially developed by Joslin et al. (2013) based on a vector of pricing factors that includes the first three principal components of yields and two macroeconomic factors (an economic activity indicator and inflation) for the Euro area. The model has the interesting feature of accommodating unspanned macro risks, feature that should be taken into account for the Euro area as economic activity and inflation are not "spanned" by the yield curve. The usual estimation of such affine term structure model is done with a two-step procedure which consists in the estimation in a first step of the historical dynamics of the pricing factors and in a second step, of the risk-neutral dynamics while taking advantage of the cross-section of yields. I improve the first step by using an estimation method inspired by Jardet et al. (2013). By taking into account unit-root constraints, cointegration

relationships among state variables and by minimizing the long-term forecast errors of the state variables, the implemented methodology provides better estimates of long-term expectations of the short rate and thus more accurate long-horizon term premium. Given the unknown nature of the premium's determinants, my estimate should be viewed as capturing any effects that might impact the price of Euro-area riskless sovereign bonds other than expected future monetary policy. Focusing on the 5Y maturity for the Eurozone, I find that the 5Y yield term premium has been hovering around 100 basis points and represent on average over the period 21% of the 5Y bond yield. All in all, under the framework of the Expectation Hypothesis, the Euro area also went through its own "Greenspan conundrum". I distinguish three noteworthy "conundra" episodes from 1999 to 2008. Similar to past US analyses, two of them took place during monetary policy tightenings decided by the ECB. The third one deserves particular attention as it took place at the same time as the US bond market's conundrum between June 2004 and December 2005. The estimated affine term structure model uncovers the potential disruptive role of the term premium in the transmission of monetary policy. The various conundra illustrate the difficulties faced by central banks in guiding interest rate expectations towards their desired path as well as in taming the term premium.

## 2 Related literature

Several papers develop yield curve models without any macroeconomic component such as the popular factor models of Duffie and Kan (1996) or Dai and Singleton (2000), in which the set of yields is explained by a few latent factors. Joslin et al. (2011) among others develop an affine term structure model with only observable factors. And finally, a number of papers model the joint dynamics of the macroeconomy and interest rates such as Ang and Piazzesi (2003). In addition to three latent factors, Ang and Piazzesi (2003) also include two macroeconomic variables extracted from the PCA (Principal Component Analysis) on a set of inflation-related measures and on another set reflecting real activity. But the majority of these macro-finance models make the implicit assumption that macroeconomic variables are actually risk factors that can be derived from yields. On the contrary, Joslin et al. (2013) introduce affine term structure models with observable yields and macro factors that accommodate unspanned macro risks (see section 3.3).

Another important issue being dealt with in the literature is the high persistence displayed by interest rates. With relatively short samples (Euro area for example), estimating correctly the historical dynamics is not straightforward and often leads to errors. Modeling it with a standard VAR would often lead to flat long-term expectations of the short rate. Kim and Orphanides (2012) manage to circumvent that problem by including survey data on long-term rates expectations so that their model-implied expectations match those of the market. Another possibility is to estimate the dynamics by properly taking into account their persistence like Jardet et al. (2013). These authors make use of averaging estimators which combine estimates resulting from a standard unconstrained VAR and those obtained with a constrained one which takes into account cointegration relationships. In this paper, I use a similar approach to estimate an affine term structure model for the Euro area.

The methodological issues mentioned above are essential to correctly study the conundrum which has been extensively explored by the literature for the US. Many contributions focus on the term premium which estimation has been very challenging. Several papers, such as Bernanke et al. (2004), Cochrane and Piazzesi (2009), Kim and Wright (2005) attempt to obtain a precise estimation of the US term premium. As for the conundrum itself, Kim and Wright (2005) find that a declining term premium was the key factor behind the puzzling behavior of long-term interest rates. In the same vein, Rudebusch et al. (2007) compare several term premium's estimates and find a similar result.

However, the structural determinants of this risk premium themselves are still not well understood and the search for these fundamental-based macroeconomic factors remains a work in progress. Piazzesi and Schneider (2007) or Bansal and Shaliastovich (2013) for example develop utility-based models for the term structure of interest rates. They both show that inflation underpins the bond risk premium. On the empirical side, the literature highlights a wide range of potential determinants found in the data (the present paper does not attempt to find them). Wright (2011) finds that inflation uncertainty is a significant determinant with a cross-country analysis. Turning again to the conundrum, Kim and Wright (2005) note that practitioners often cite several possible factors. Better-anchored inflation expectations with a reduction in macro volatility are one plausible explanation. Analysts also cite the increased foreign interest in US long-term bonds. Moreover, Rudebusch and Swanson (2008) underline the significant role of some "out-of-model" variables during the conundrum such the volatility of long-term treasury yields, foreign official purchase of Treasury bonds etc. Generally speaking, supply/demand adequation can be said to be the main cause of the conundrum in the US but remain to be fully incorporated in a term structure model.

### 3 A term structure model with macro factors

#### 3.1 Term premium

Financial theory states that the term structure of interest rates is governed by what is usually called the "Expectation Hypothesis" (EH). According to this hypothesis, the expected return an investor expects from holding a long-term bond until maturity is the same as the expected return one gets when rolling over a series of short-term bonds. Equivalently, the long-term yield is equal to the average expected short-term yield. Unfortunately, with risk-averse investors, this hypothesis is unlikely to hold, given that a compensation may be required by them in order to hold such bond. The term premium refers exactly to this compensation for bearing the risk of variation in the riskless rate. In this paper, I will only consider the following term premium:

$$Yield\ premium : YTP_t^n = y_t^n - \frac{1}{n} \sum_{i=0}^{n-1} \mathbb{E}_t(r_{t+i}) = y_t^n - Exp_t^n \quad (1)$$

Here  $r_t$  denotes the short rate i.e. the one-period yield  $y_t^1$ ,  $y_t^n$  the yield of a  $n$ -period zero-coupon bond and  $Exp_t^n = \frac{1}{n} \sum_{i=0}^{n-1} \mathbb{E}_t(r_{t+i})$ , the expected average path of the short rate over the next  $n$  periods.

### 3.2 The general setup

Following Ang and Piazzesi (2003), I present below the standard discrete-time affine term structure model used as the basis for the paper's model that incorporates unspanned macro risks as developed in Joslin et al. (2013).

Let  $P_t$  be a  $N_1$ -dimensional vector of pricing factors,  $M_t$  a  $N_2$ -dimensional vector of macro factors ( $N = N_1 + N_2$ ) and  $Z_t = [P_t, M_t]$ . Provided the agents value nominal bonds using a restricted set of factors that takes into account all risks in the economy, the short rate may be modeled, by the following equation:

$$r_t = \rho_0 + \rho_1 Z_t \quad (2)$$

As in standard affine term structure models, I suppose the factors  $Z_t$  follow a first-order Gaussian VAR<sup>1</sup> under the probability measure  $\mathbb{P}$ :

$$\Delta Z_t = K_{0Z}^{\mathbb{P}} + K_{1Z}^{\mathbb{P}} Z_{t-1} + \Sigma_Z \varepsilon_{Z_t}^{\mathbb{P}} \quad (3)$$

where  $\varepsilon_{Z_t}^{\mathbb{P}} = \varepsilon_t \sim N(0, I_N)$  and  $\Sigma_Z$  is a non-singular  $N \times N$  matrix.

Under the assumption of complete markets and no arbitrage, there exists a risk-neutral probability measure that is equivalent to the physical measure (see Appendix A for more details). Under the risk-neutral measure, the state vectors follow an alternative law of motion:

$$\Delta Z_t = K_{0Z}^{\mathbb{Q}} + K_{1Z}^{\mathbb{Q}} Z_{t-1} + \Sigma_Z \varepsilon_{Z_t}^{\mathbb{Q}} \quad (4)$$

with  $(K_{0Z}^{\mathbb{Q}}, K_{1Z}^{\mathbb{Q}})$  both linearly related to  $(K_{0Z}^{\mathbb{P}}, K_{1Z}^{\mathbb{P}})$  by the market prices of risk. (see Appendix A.2 for further details). Under the risk-neutral measure, states of the world in which investor's marginal utility is high are in fact outweighed compared to the situation in the physical world.

Within a risk-neutral pricing framework, the price of a zero-coupon bond can be written simply as:

$$p_t^n = \mathbb{E}_t^{\mathbb{Q}} \left[ \exp \left( - \sum_{i=0}^n r_{t+i} \right) \right] \quad (5)$$

Plugging Equation (2) into Equation (5), bond prices can be expressed as exponential affine functions of the state variables:

$$p_t^n = \exp \left( \overline{A}_n + \overline{B}_n' Z_t \right) \quad (6)$$

where the coefficients  $\overline{A}_n$  is a scalar and  $\overline{B}_n$  is a  $N \times 1$  vector for a given maturity. The continuously-compounded bond yield  $y_t^n$  is therefore:

---

<sup>1</sup>I choose in the paper to only consider a VAR(1)-based affine term structure model for parsimony. This setting makes the estimation of the model easier and faster. Richer dynamics are possible but the number of parameters might significantly increase. Moreover, a VAR(p) can still be written as a VAR(1).

$$y_t^n = A_n + B_n' Z_t \quad (7)$$

with  $A_n = -\overline{A}_n/n$  and  $B_n = -\overline{B}_n/n$ .

### 3.3 A model with unspanned macro risks

Given Equation (7), both the pricing factors  $P_t$  and the macro factors  $M_t$  determine the model-implied bond yields. With the bond yields as given, one would be able to solve for the factors using (7) and would conclude that  $M_t$  is "spanned" by bond yields, i.e. perfectly replicated such as

$$M_t = a_0 + a_1' P_t \quad (8)$$

However, empirical results (see Ludvigson and Ng (2009) for example) show that macro factors (such as economic growth and inflation) are only partially explained by  $P_t$ , which is actually in line with the general conception that risks ranging from financial to labor markets, and not only sovereign bond yields, impact real economic growth.

Equation (8) also implies that after conditioning on the current yield curve, the macro variables  $M_t$  are supposed to have no additional information content on risk premiums and future values of  $M_t$ . Again, as Joslin et al. (2013) already emphasize, this feature is in contradiction with the vast literature on business cycle forecasting.

Furthermore, as the cross section of bond yields is actually well explained by a very small number of factors (typically the level, slope and curvature for most developed bond markets), the standard term structure model presented above, with its additional spanned macro factors, is also plagued by a poor goodness-of-fit as noted by Joslin et al. (2013).

The several issues associated with the spanned macro factors of the standard model hint that the initial framework is somehow flawed. Joslin et al. (2013) suggest that what has to be reconsidered is the hypothesis that the discount factor agents use to price bonds is fully responsive to macro risks. If we assume now that agents' pricing kernel results from the projection of the economy-wide kernel (based on  $Z_t$ ) on the limited set of factors that explains the term structure of the yield curve (only  $P_t$ ) instead, then the issues raised above become irrelevant. Under this modified framework, the new SDF prices the entire yield curve but not all macro risks which are now "unspanned" by information on the yield curve, i.e. imperfectly correlated.

As developed in Joslin et al. (2013)<sup>2</sup>, the new assumption entails that Equation (2) and (4)<sup>3</sup> become

$$r_t = \rho_0 + \rho_{1P} P_t \quad (9)$$

$$\Delta P_t = K_{0P}^Q + K_{1P}^Q P_{t-1} + \Sigma_P \varepsilon_{P_t}^Q \quad (10)$$

---

<sup>2</sup>Like these authors, I also suppose that the inclusion of spanned or unspanned macro factors in the affine term structure model is independent of the issue of bond yields' or macro factors' measurement errors.

<sup>3</sup>In this paper, I will only model the risk-neutral dynamics without modeling the market prices of risk which would create a direct link between the historical and risk-neutral dynamics.

with  $\rho_{1P}$  and  $K_{0P}^{\mathbb{Q}}$  two  $N_1$ -dimensional vectors,  $K_{1P}^{\mathbb{Q}}$  a  $N_1 \times N_1$  matrix,  $\Sigma_P \Sigma'_P$  the  $N_1 \times N_1$  upper-left block of  $\Sigma_Z \Sigma'_Z$  and  $\varepsilon_{P_t}^{\mathbb{Q}} \sim N(0, I_{N_1})$ .

It can be shown that under the new framework, the last  $N_2$  elements of  $B_n$  are equal to 0. Thus, Equation (7) is equivalent to

$$y_t^n = \widetilde{A}_n + \widetilde{B}_n' P_t \quad (11)$$

where  $\widetilde{A}_n$  and  $\widetilde{B}_n$  are deduced from recursive equations (see Appendix A.2).

In general, affine term structure models provide a simple and flexible framework to study the term structure of interest rates but as the literature previously underlined (see Gurkaynak and Wright (2012)), these simple representations are not based on any structural foundations. Moreover, by introducing unspanned macro factors in the model, I actually assume that the pricing kernel of economic agents does not fully price macro risks. Overall, though having shortcomings, I believe that the model with unspanned macro factors presented here provides a flexible, simple, and parsimonious way to study the term structure of risk-free interest rates in the Eurozone while taking into account important economic features of the term premium in the Eurozone's bond market.

## 4 The data

### 4.1 Yield data

I use data on monthly zero-coupon bond yields of maturities 6, 12, 24, 36, 60, 84 and 120 months from January 1999 to August 2008. The short-term rate used throughout the paper is the 1-month OIS rate rather than the 1-month Euribor in which non-negligible liquidity and credit risk premia are priced. Until September 2004, I use the German sovereign yield curve (provided by the Bundesbank) as representative of the Euro area risk-free interest rates. From October 2004 to August 2008, zero-coupon bond yields provided by the ECB for the Eurozone AAA countries are used in this paper. All yield data are end-of-month. Some of the sovereign yields are plotted in Figure 1.

According to Joslin et al. (2011),  $P_t$  can be rotated to become the principal components of bond yields. A PCA shows that the first three principal components of bond yields explain 99.9% of the cross-sectional variation. I choose to use the first  $N_1 = 3$  PCs of bond yields<sup>4</sup>, that are usually interpreted as the level, slope and curvature of the yield curve as the yield pricing factors  $P_t$ .

Table 1 reports some descriptive statistics of the various bond yields used in the sample.

---

<sup>4</sup>Like others in the literature (Joslin et al. (2013) for example), I rescale the principal components obtained from the PCA. we denote  $l_{j,i}$  the loading on yield  $i$  in the construction of  $PC_j$ , the PCs have been rescaled so that: (1)  $\sum_{i=1}^8 l_{1,i}/8 = 1$ , (2)  $l_{2,10Y} - l_{2,6M} = 1$  and (3)  $l_{3,10Y} - 2l_{3,2Y} + l_{3,6M} = 1$ . This way, the PCs are on a similar scale. All the variables I will be using take on values in  $[-3\%, 8\%]$ .

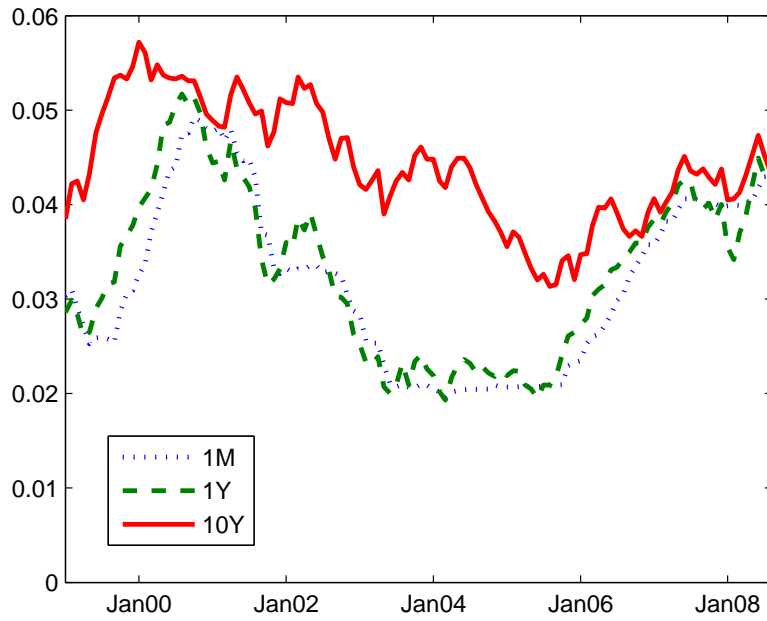

Figure 1: Eurozone historical zero-coupon bond yields for three different maturities.

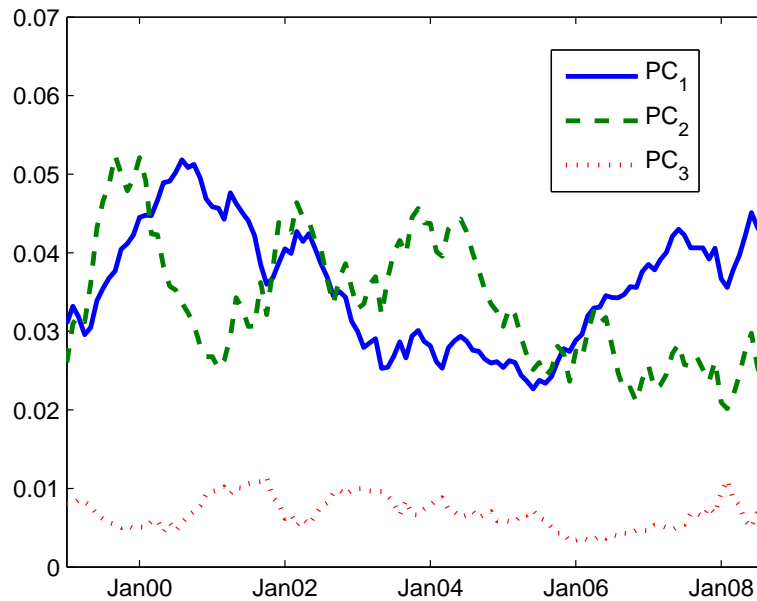

Figure 2: Historical series of the first three principal components of bond yields from 1999 to Aug 2008.

## 4.2 Macro variables

I use two macro variables in the model. The first one is the Economic Sentiment Indicator for the Euro area (rescaled)<sup>56</sup>, published every month by the European Commission, which is to capture

<sup>56</sup>The ESI is issued following harmonized surveys by the European Commission for different sectors of the economy in the European Union. Industry (manufacturing), services, retail trade and construction sectors, as well as consumers

Yields	1M	6M	1Y	2Y	3Y	5Y	7Y	10Y
Mean	0.032	0.032	0.033	0.035	0.036	0.039	0.042	0.044
SD	0.009	0.009	0.009	0.008	0.008	0.007	0.007	0.006
Skewness	0.264	0.253	0.183	0.132	0.143	0.177	0.137	-0.001
Kurtosis	1.844	1.964	1.935	1.955	2.007	2.114	2.181	2.180
Min	0.020	0.019	0.019	0.020	0.022	0.025	0.028	0.031
Max	0.049	0.051	0.052	0.053	0.053	0.053	0.055	0.057

Table 1: Summary statistics on Euro Area monthly zero-coupon bond yields. Period: 1999M1-2008M8

real activity. The second one is the Euro-area monthly year-on-year inflation (HICP, overall index).<sup>7</sup> Figure 3 plots the two variables.

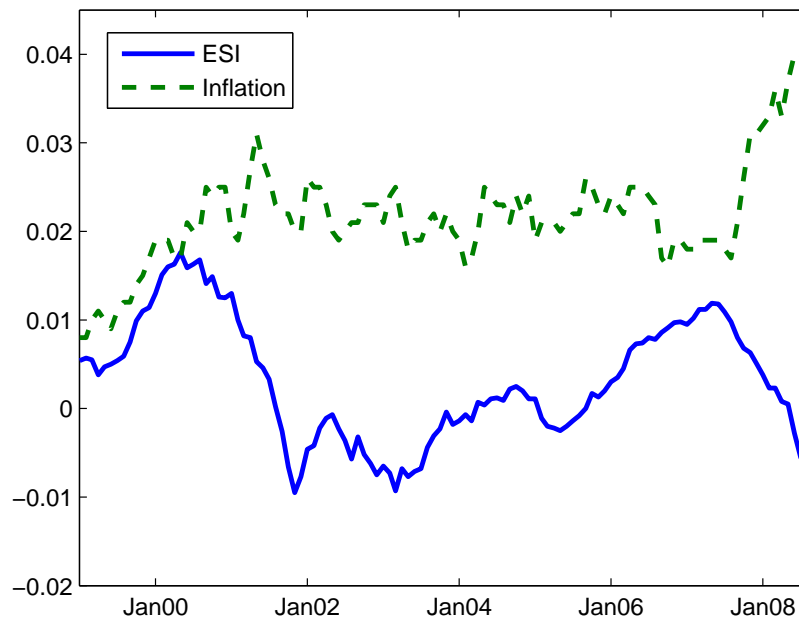

Figure 3: Time series of Euro-area inflation and of the Economic Sentiment Indicator from 1999 to Aug 2008.

To assess the need for a model that accommodates "unspanned" macro risks, we can check how well the macro factors are explained by the *PCs*. With the present data sample, the projection contribute to the indicator. The raw indicator is rescaled so that the variable take on values in  $[-2\%, 4\%]$

<sup>6</sup>Other activity-related indicators can be used such as the Eurozone industrial output or even an estimated monthly real GDP growth.

<sup>7</sup>As monetary policy in the Euro area is based on the macroeconomic conditions, it is relevant to consider economic indicators that cover the whole monetary union, instead of the AAA-rated countries only.

	Activity ( <i>Act</i> )	Inflation ( <i>Inf</i> )
Mean	0.003	0.021
SD	0.007	0.006
Skew	0.180	0.578
Kurtosis	2.122	4.637
Min	-0.010	0.008
Max	0.018	0.04

Table 2: Summary statistics on Euro area macroeconomic factors. Period: 1999M1-2008M8

of real activity on the first three *PCs* of yields gives an adjusted  $R^2$  of 55% and the projection of inflation 15%. Thus almost 45% of the variation in activity and 85% of inflation are not related to the yields' *PCs*.

Projections of changes in activity and inflation onto changes in the three *PCs* give even smaller adjusted  $R^2$  (21% and 1% respectively). All in all, accommodating unspanned macro risks in the Gaussian term structure model is welcomed.

## 5 Estimation

### 5.1 First approach

The methodology used for the estimation of the model closely follows Joslin et al. (2013) but without the reparametrization detailed in Joslin et al. (2011), which reduces the number of parameters to be estimated and allows for faster computation. Nevertheless, I choose to stick to a standard procedure which will be detailed below to keep the model simple. The parameters to be estimated are included in the following equations under the risk-neutral measure:

$$r_t = \rho_{0P} + \rho_{1P}P_t \quad (12)$$

$$\Delta P_t = K_{0P}^{\mathbb{Q}} + K_{1P}^{\mathbb{Q}}P_{t-1} + \Sigma_P \varepsilon_{P_t}^{\mathbb{Q}} \quad (13)$$

And under the physical measure:

$$\Delta Z_t = K_{0Z}^{\mathbb{P}} + K_{1Z}^{\mathbb{P}}Z_{t-1} + \Sigma_Z \varepsilon_{Z_t}^{\mathbb{P}} \quad (14)$$

In the model, the  $Z_t$  are priced without errors ( $Z_t = Z_{t,o}$ ) whereas the zero-coupon bond yields equal their model-implied counterparts plus mean zero, normally distributed errors. As Joslin et al. (2013) relevantly notice, the absence of constraints linking the physical and risk-neutral measures allows me to separate the time-series properties of  $Z_t$  in the physical world from the cross-sectional

constraints imposed by the no-arbitrage condition. The conditional likelihood function (under  $\mathbb{P}$ ) of the observed data  $(y_{t,o}^n)$  can be written as:

$$f(y_{t,o}^n | y_{t-1,o}^n, Z_{t-1}; \Theta) = f(y_{t,o}^n | Z_t; \rho_{0P}, \rho_{1P}, K_{0P}^Q, K_{1P}^Q, \Sigma_P) * f(Z_t | Z_{t-1}; K_{0Z}^P, K_{1Z}^P, \Sigma_Z) \quad (15)$$

As mentioned earlier, I suppose the yields on zero-coupon bonds  $y_{t,o}^n$  equal their model-implied values  $y_{t,m}^n = \widetilde{A}_n + \widetilde{B}_n' P_t$  plus mean zero, i.i.d. and normally distributed errors  $\eta_t = y_{t,o}^n - y_{t,m}^n$ , which entails:

$$f(y_{t,o}^n | Z_t; \rho_{0P}, \rho_{1P}, K_{0P}^Q, K_{1P}^Q, \Sigma_P) = (2\pi)^{-(J-N)/2} |\Sigma_\eta|^{-1} \times \exp\left(-\frac{1}{2} \|\Sigma_\eta^{-1} \times (\eta_t)\|^2\right) \quad (16)$$

Using the assumption that  $Z_t$  is conditionally Gaussian, the second term can be expressed as:

$$f(Z_t | Z_{t-1}; K_{0Z}^P, K_{1Z}^P, \Sigma_Z) = (2\pi)^{-N/2} |\Sigma_Z|^{-1} \times \exp\left(-\frac{1}{2} \|\Sigma_Z^{-1} \times (Z_t - \mathbb{E}_{t-1}[Z_t])\|^2\right) \quad (17)$$

where  $\mathbb{E}_{t-1}[Z_t] = K_{0Z}^P + (I + K_{1Z}^P) Z_{t-1}$ ,  $J$  is the total number of yield maturities and where for a vector  $x$ ,  $\|x\|^2$  denotes the Euclidean norm squared  $\sum x_i^2$ .

The (conditional on  $t = 0$ ) log-likelihood function is therefore the sum:

$$L = \sum_{t=1}^T \left[ \log \left[ f(y_{t,o}^n | Z_t; \rho_{0P}, \rho_{1P}, K_{0P}^Q, K_{1P}^Q, \Sigma_P) \right] + \log \left[ f(Z_t | Z_{t-1}; K_{0Z}^P, K_{1Z}^P, \Sigma_Z) \right] \right] \quad (18)$$

Parameters in Equation (3) can be estimated from time series without considering cross-sectional restrictions : if  $Z_t$  is priced perfectly by the model ( $Z_{t,o} = Z_t$ ), Joslin et al. (2013) prove that the ML estimates of  $(K_{0Z}^P, K_{1Z}^P)$  are actually given by the OLS estimation of the  $VAR(1)$  process  $Z_t$ <sup>8</sup> and are independent of  $(\Sigma_P, \Sigma_Z)$ . The remaining parameters of the model  $(\rho_{0P}, \rho_{1P}, K_{0P}^Q, K_{1P}^Q, \Sigma_Z)$  are then estimated by maximum log-likelihood, assuming the observed bond yields are measured with an i.i.d Gaussian error.<sup>9</sup> I choose here not to take into account the internal-consistency constraint which requires model-implied yields to reproduce the  $PCs$ . Nevertheless, I check that the constraint actually holds *ex-post*.<sup>10</sup>

## 5.2 Near-cointegrated VAR (NCVAR)

Interest rates are well-known to be highly persistent and given the short range of data at my disposal on the Eurozone yield curve, bias can easily arise in the estimation of the historical dynamics of interest rates. Because of high persistence in the data, I face what the literature usually calls

<sup>8</sup>Actually, though additional lags should be considered in light of standard lag selection procedures, our sample is too limited in size. Nevertheless, if I consider a  $VAR(2)$  process for  $Z_t$ , the estimation shows most coefficients of  $Z_{t-2}$  are not significantly different from 0. Thus, my  $VAR(1)$ -based model is still preferable.

<sup>9</sup>See Appendix C.2

<sup>10</sup>I find a RMSE of 1.7 bps which means the internal constraint holds *ex-post*.

the "discontinuity problem", which is the huge difference between predictions (especially long-run forecasts of persistent variables) based on unconstrained VAR models and those taking into account unit-roots and cointegration relationships.

The approach I use to solve these issues is largely drawn from Jardet et al. (2013) and introduces "Near-Cointegrated VARs" (NCVAR) to get better estimations of long-run expectations, using averaging estimators. I call "CVAR" the model under the historical measure estimated under a VECM framework.

### 5.2.1 Unit roots and VECM model

Standard unit-root tests reveal that the first  $PC$ , which is a proxy for the level of the yield curve, is closer to a  $I(1)$  process or at least very persistent, as well as  $PC_2$  and  $Inf$ . Results are more mixed for  $PC_3$  and the activity factor but given KPSS and ERS's superior power to the ADF test,  $PC_3$  and  $Act$  are closer to stationarity. In the end, choosing a simple VAR to model the historical dynamics of  $Z_t$  will most likely lead to significant estimation bias, given the high persistence and potential cointegration relationships among the five state variables.

The historical dynamics of the factors which is described through Equation (3) can be directly interpreted as a vector error correction model (VECM). I determine the rank  $r$  of matrix  $K_{1Z}^{\mathbb{P}}$  with a Johansen cointegration test using a trace and maximum eigenvalue tests.  $r$  actually represents the number of cointegrating relationships among the state variables.

By choosing to write the VECM with Equation (3), I actually make the implicit hypothesis that there's a linear trend in  $Z_t$  or/and an intercept in the cointegrating component<sup>11</sup>. Equation (3) can be rewritten as:

$$\Delta Z_t = \alpha (\beta' Z_{t-1} + c_0) + \Sigma_Z \varepsilon_{Z_t}^{\mathbb{P}} \quad (19)$$

or

$$\Delta Z_t = \alpha (\beta' Z_{t-1} + c_0) + c_1 + \Sigma_Z \varepsilon_{Z_t}^{\mathbb{P}} \quad (20)$$

with the decomposition  $K_{0Z}^{\mathbb{P}} = \alpha c_0$  ( $K_{0Z}^{\mathbb{P}} = \alpha c_0 + c_1$  respectively).<sup>12</sup> Under the restricted specification (19), the trace and eigenvalue tests both point to the same rank of cointegration. Both tests accept the presence of  $r = 2$  cointegrating relations. Therefore, I can write  $K_{1Z}^{\mathbb{P}} = \alpha \beta'$  where

---

<sup>11</sup>Critical values of the Johansen test actually depend on the assumptions made concerning the cointegrating relations and the VECM which are:

- absence or presence of an intercept/trend in the cointegrating relations
- absence or presence of an intercept in the VECM (which is equivalent to a linear trend in the data. I choose to neglect quadratic trends).

<sup>12</sup>Actually, though additional lags should be considered in light of standard lag selection procedures, our sample is too limited in size. Nevertheless, if I consider a VECM for  $Z_t$  that also includes  $\Delta Z_{t-2}$ , the estimation shows most coefficients of this term are found to be not significantly different from 0. Thus, my simple VECM is still preferable.

$\alpha$  is a  $(5 \times 2)$  adjustment coefficient vector and  $\beta$  a  $(5 \times 2)$  cointegrating vector. The cointegration analysis was based on the model with a restricted constant so I still have to test the hypothesis  $H_0 : K_{0Z}^{\mathbb{P}} = \alpha c_0$  against its alternative  $H_a : K_{0Z}^{\mathbb{P}} = \alpha c_0 + c_1$  using a  $\chi^2(3)$ -distributed likelihood ratio statistic (see Johansen (1995)) to confirm that specification (19) is the most appropriate one. The test confirms specification (19) and therefore tells us that there's no drift in the common trend.<sup>13</sup>

### 5.2.2 Averaging estimators

Averaging estimators were first proposed by Hansen (2010). The idea consists in combining two different kinds of estimators. Firstly, I estimate the parameter  $\theta_{UNC}$  of the unconstrained VAR with one lag representing the historical dynamics of the factors by OLS. In a second step, I proceed with the estimation of a one-lag VECM of the state variables (therefore imposing unit-root constraints), which gives the parameter vector  $\theta_{CON}$ . The averaging estimator that specifies the Near-cointegrated VAR is then defined as:

$$\theta_{NCVAR} = \theta_{NCVAR}(\lambda) = \lambda\theta_{UNC} + (1 - \lambda)\theta_{CON} \quad (21)$$

with  $\lambda \in [0, 1]$  a parameter used to minimize a chosen criterion.

Given that the short rate will depend on the yields' *PCs* as stated in Equation (9), I choose to focus on minimizing the forecast error (RMSFE) when predicting the *PCs*. As the objective is to provide a more precise estimation of the term premium, I could have actually minimized the error in forecasting the short-rate or  $Exp_t^n$ , given the definition of  $YTP_t^n$  in the paper. Jardet et al. (2013) base their criterion on  $\mathbb{E}_t^{\mathbb{Q}}[\exp(-(r_t + \dots + r_{t+h-1}))]$ , thus having at disposal more points for the computation of the criterion. Both alternative approaches would have been more relevant but computationally more intensive in the present framework as  $\lambda, \rho_0, \rho_1$  and the parameters governing the historical/neutral dynamics of the state variables would have to be estimated simultaneously. So the present approach can benefit from the two-step estimation speed.

So for a forecast horizon  $h$ , the parameter  $\lambda(h)$  is selected through the following minimization program:

$$\lambda^*(h) = \arg \min_{\lambda \in [0, 1]} \sum_i \left[ \sum_t \left( P_{i,t+h} - \mathbb{E}_t^{implied} [P_{i,t+h}] \right)^2 \right] \quad (22)$$

where  $P_{i,t+h}$  is the observed realization of the  $PC_i$  for each date  $t$  and horizon  $h$  whereas  $\mathbb{E}_t^{implied} [P_{i,t+h}]$  is the model-implied prediction of the  $PC_i$ . The criterion is just (up to a factor) the standard *TMSFE* (Trace Mean Square Forecast Error).

Like for a conventional out-of-sample forecasting exercise, I first estimate  $\theta_{UNC}$  and  $\theta_{CON}$  over the period 1999M1-2002M08<sup>14</sup> and compute  $\hat{P}_{t+h}$  with  $t = 2002M08$ . For each later date  $t$ , I re-

<sup>13</sup>The likelihood ratio statistic is  $LR = -T \sum_{j=3}^5 \log \left[ \frac{(1 - \tilde{\lambda}_j)}{(1 - \lambda_j)} \right]$  where  $(\lambda_j, \tilde{\lambda}_j)$  are the smallest eigenvalues associated to the maximum likelihood estimation of the unrestricted and restricted model respectively. I find  $LR = 0.830$  which is much lower than  $\chi_{0.01}^2(3) = 11.35$

<sup>14</sup>I am clearly aware that the initial window is very narrow for an estimation of the historical dynamics but the relative short existence of the Eurozone leaves me with no other choice than using this short time span so that I can

estimate  $\theta_{UNC}$  and  $\theta_{CON}$  over the expanded window and compute the model-implied forecast value of the  $PCs$ . This methodology replicates the typical behavior of an investor that incorporates new information over time. The out-of-sample forecasts are performed for  $t \in [2002M09, 2008M08 - h]$ .

In the end, as I am interested in long-term risk premium,  $h$  is set equal to 60 months given the limited time length of the data and the optimization yields  $\lambda = 0.3042$  with the Trace Root Mean Square Forecast Error (TRMSFE) being equal to 82 bps<sup>15</sup>, while for the VAR-based model  $TRMSFE_{VAR} = 109$  bps and  $TRMSFE_{CVAR} = 158$  bps for the CVAR-based one. This estimated value for  $\lambda$  implies that  $\theta_{NCVAR}$  is something closer to  $\theta_{CON}$  than the VAR-based estimator.

## 6 Results

### 6.1 Parameters estimates

$(\rho_0, \rho_{1P}, K_{0P}^{\mathbb{Q}}, K_{1P}^{\mathbb{Q}}, K_{0Z}^{\mathbb{P}}, K_{1Z}^{\mathbb{Q}}, \Sigma_Z)$ <sup>16</sup> are initiated at the values obtained from the estimations of the associated standard VARs. Maximization of the log-likelihood and computation of the asymptotic standard errors (for the short-rate and risk-neutral parameters) are performed using the quasi-Newton algorithm available in the Matlab software. Estimates for  $(\rho_0, \rho_{1P}, K_{0P}^{\mathbb{Q}}, K_{1P}^{\mathbb{Q}})$  are highly significant because the estimation takes advantage of the large cross-sectional information on yields. In the end, the root mean square fitting error of yields is extremely low (around 1 bp), indicating that the first three  $PCs$  are able to account for almost all cross-sectional variation in yields thus proving that the specification of the  $\mathbb{Q}$ -dynamics of bond yields reflected in Equation (4) and (11) is appropriate for Eurozone data. Observed and model-implied yields almost coincide. For instance, the difference between the observed and model-implied 5Y bond yield never exceeds 7 bps.

### 6.2 Estimation of the term premium

I attempt now to provide an estimate of the Eurozone term premium for the 5Y horizon as the averaging estimator was optimally chosen for this maturity.<sup>17</sup> First of all, Figure 4 shows the difference obtained for the model-implied 5-year average expected path of the short rate  $Exp_t^{5Y} = \frac{1}{60} \sum_{i=0}^{60-1} \mathbb{E}_t(r_{t+i})$  between a simple model without any macro factors, with spanned macro factors and our baseline NCVAR-based that includes unspanned macro risks. As it is shown in the figure, the unspanned estimate significantly deviates from the other two, especially in 2007-2008. The first two models fail to capture the important fall at the end of the sample. Figure 5 compares instead the different versions based on the VAR-, CVAR- (VECM) and NCVAR-based models with unspanned macro factors. As mentioned earlier, using a simple VAR-based term structure model would lead to

---

at least consider 5-year-ahead expectations of the  $PCs$  for the estimation strategy.

<sup>15</sup>The estimate of  $\lambda$  stays robust after slight changes to the initial time window (see Appendix for details).

<sup>16</sup>Tables in Appendix C.4 give the estimated parameters of the term structure model based on the previously described NCVAR method

<sup>17</sup>Past US studies focused on the 10-year maturity. Unfortunately, due to limitations on the data, I can only consider the 5-year horizon.

a rather flat 5Y average expected short rate path while the one based on the CVAR model is much more volatile.

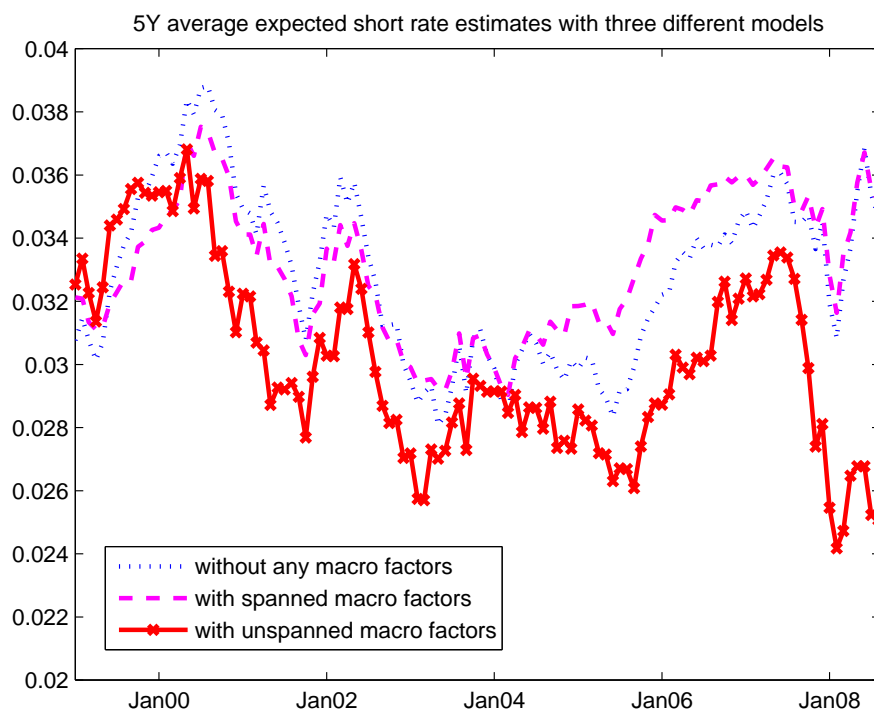

Figure 4: 5-year average expected path of the short rate extracted from a model without macro factors (blue dotted line), with spanned macro factors (magenta dashed line) and from the baseline NCVAR-based model with unspanned macro factors (red solid line with cross markers)

Turning to the term premium, Figure 6 once again reveals the discrepancy between the no-macro/spanned term structure models and our baseline that includes unspanned macro factors. The no-macro and spanned estimate dive clearly into negative territory at the end of the American "Greenspan Conundrum". The significant deviation in 2007-2008 is also particularly striking as the baseline estimate strongly rises until August 2008. Obviously, omitting macro factors or enforcing the macro-spanning constraint lead to inaccurate model-implied term premia. Indeed, in both cases, after conditioning on the current yield curve, macro variables are assumed to be uninformative about risk premium. Finally, Figure 7 shows instead the 5Y term premium obtained with the model based on a VAR, CVAR and NCVAR processes. The figure typically illustrates once again the differences between the three methodologies with the VAR-based premium being much more volatile than the others for instance.

On average over the whole sample, the 5Y term premium in the model is estimated to represent 21% of the 5Y yield. It has therefore the potential to disturb the transmission of monetary policy in the Euro area.

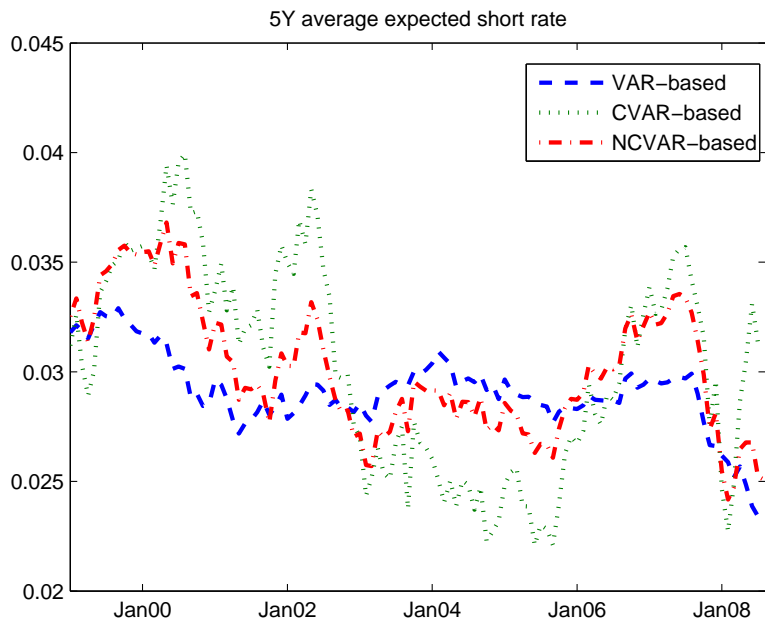

Figure 5: Expected average path of the short rate over a 5-year horizon estimated with the VAR-based (blue dashed line), the NCVAR-based (red dash-dotted line) and the CVAR-based models (green dotted-line).

## 7 Was there a bond yield conundrum in the Euro area ?

### 7.1 A first look

Under the assumption of the Expectation Hypothesis, long rates should be responsive to any change in the short rate and its expected average path. What triggered the debate around the Greenspan conundrum was the muted response of long rates after the successive rate hikes decided by the FED between 2004 and 2006. Thus, in this parallel analysis, I check whether or not the Euro area also experienced the same pattern during its monetary tightening episodes. Figure 8 shows how the 5Y rate evolved throughout the sample's period compared with its two components ( $Exp_t^{5Y}$  and  $YTP_t^{5Y}$ ) and  $r_t$  as estimated with the NCVAR model. At first sight, at the start of the first episode of tightening, from November 1999 to March 2000, the short-term interest rate rose while the 5Y interest rate increased somewhat to around 5.20% with a stagnant  $Exp_t^{5Y}$  and a volatile  $YTP_t^{5Y}$  in the background.

What happened during the second episode is slightly different. A first phase can be distinguished with both yield components moving hand in hand in the same direction following the tightening. The second phase (June 2007 - January 2008) witnesses another puzzling phenomenon: the short rate is stable while the model-implied 5Y yield falls from 4.41% to 3.60%. The expectation component's puzzling behavior and its subsequent drop seem to have exceeded the term premium's change which was not high enough to compensate for the fall of the former.

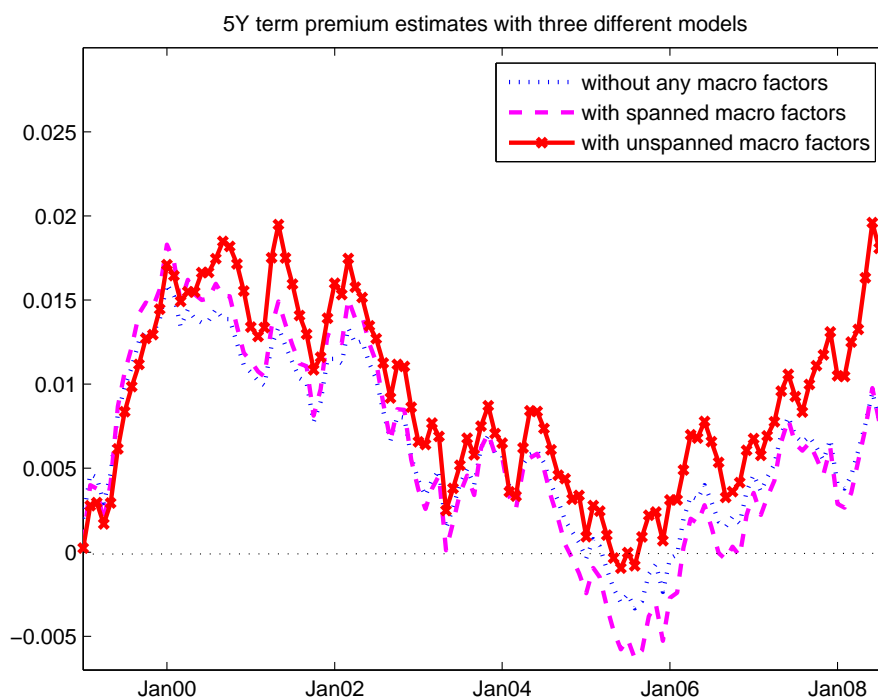

Figure 6: 5-year term premium extracted from a model without macro factors (blue dotted line), with spanned macro factors (magenta dashed line) and from the baseline NCVAR-based model with unspanned macro factors (red solid line with cross markers)

Apart from these periods discussed above from which a parallel has been drawn with past analyses on the US bond market, Figure 8 reveals an intriguing event. From June 2004 to December 2005, while the US bond market was experiencing its "Greenspan conundrum", the Euro area was also going through its own "euro-conundrum" simultaneously. The short rate was stable during that period but the 5Y bond yield fell dramatically from 3.70% to 2.94%. Turning to the sub-components, the term premium was apparently the major contributor to this significant fall.

Under the framework of the EH and mirroring past US analyses, we see that the Euro area experienced at least three noteworthy phases of puzzling behaviors which we can dub "euro-conundra": two of them displaying odd responses from bond yields after rate hikes in a similar fashion to the US experience and a third one which took place simultaneously with the Greenspan conundrum. In all these episodes, the model's term premium apparently played a significant role, which I will properly disentangle below.

## 7.2 Contribution analysis

Figure 9 plots the contributions of both the expectation ( $Exp_t^{5Y}$ ) and the term premium component ( $YTP_t^n$ ) of the 5Y bond yield during the first phase which was described earlier. The figure

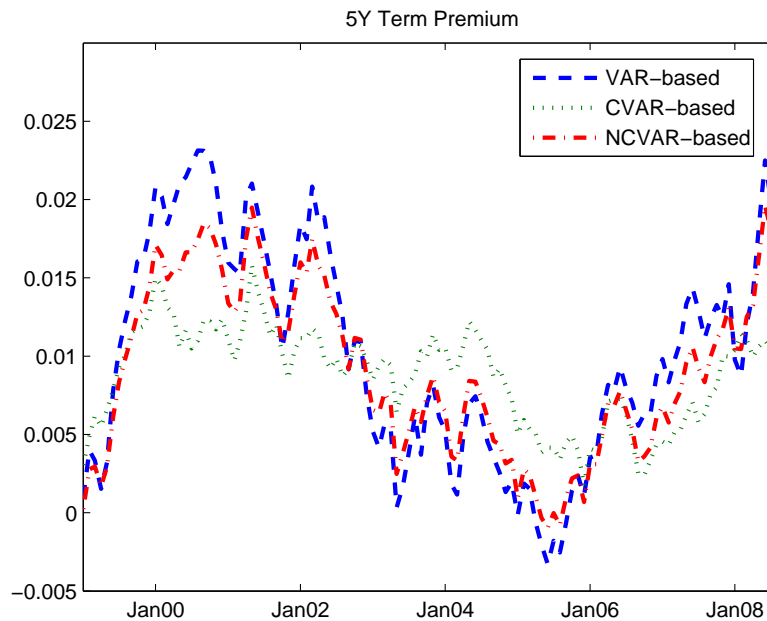

Figure 7: 5-year yield term premium estimated with the VAR-based (blue dashed line), the NCVAR-based (red dash-dotted line) and the CVAR-based models (green dotted-line).

confirms the dominant contribution of the 5Y term premium at first to the puzzling behavior of the associated bond yield which did not actually follow the average expected path of the short rate. Similar to what was found by the literature in the US, these movements of the 5Y yield we witnessed at the beginning of the monetary tightening was primarily driven by the term premium according to the model. As our estimate of the term premium is supposed to capture any effect that can impact sovereign bonds' prices, it is difficult to attribute one precise reason for this significant contribution of the risk premium. At least, given the stability of the average expected path of the short rate, the expected monetary policy effect must have been entirely captured by the term premium instead.

Turning to the second tightening episode in Euro-area history, Figure 10 plots again the contributions of both components associated to the 5Y bond yield. As suspected earlier, the fall of the long rate is actually due to investors' long-term expectations of the path of  $r_t$ . This tightening actually stands out as the financial crisis began to slowly spread to the Eurozone. Investors believed the ECB could not hold for long their strong tightening monetary stance. Thus, it seems they changed their long-term expectations of the short rate's path in the future and already expected for a more accommodative policy from the ECB.

The most interesting period in the Euro-area bond market is probably the one when the "Greenspan conundrum" actually took place at the same time in the US bond market. In Figure 11, the orientation and length of the red bars show the significant impact of the 5Y term premium on the dramatic fall of the associated bond yield during that period even though the monetary policy rate was flat all that time. Again, given the large scope of effects captured by the term premium estimate, it is

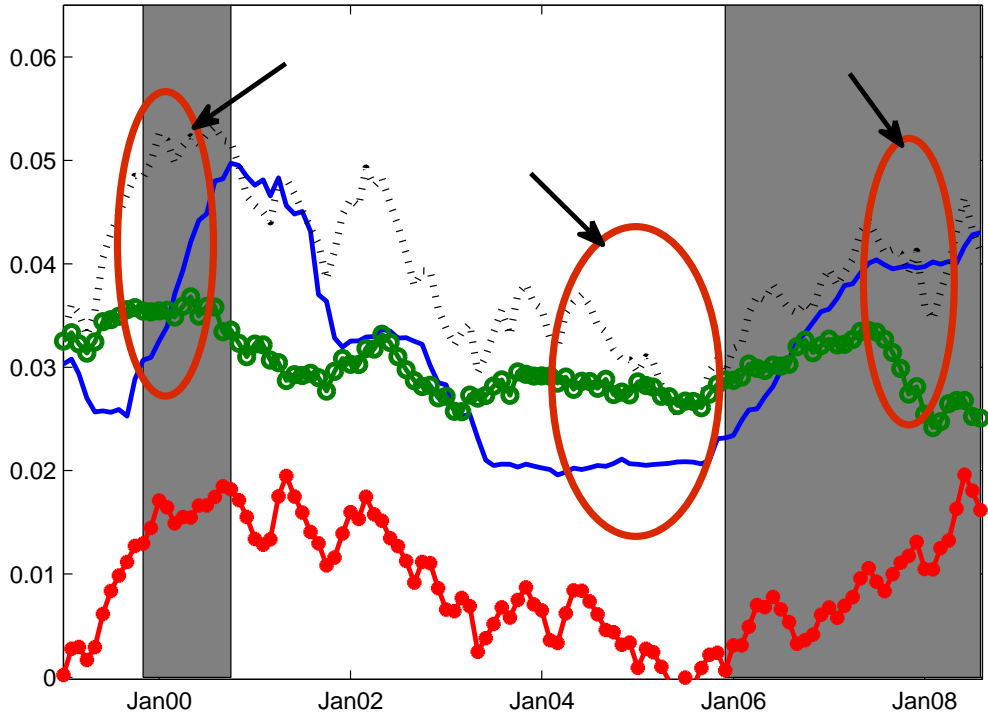

Figure 8: Evolution of the model-implied short rate (solid line),  $y_t^{5Y}$  (model-implied, dotted line),  $Exp_t^{5Y}$  (model-implied, solid line with hollow circle markers) and  $YTP_t^{5Y}$  (model-implied, solid line with full circle markers) over the Eurozone's previous monetary tightening episodes (shaded in grey).

difficult to uncover the true factors that caused this conundrum at the same time as the American one.

As in the previous sections, I check the results obtained with a no-macro term structure model.<sup>18</sup> In contrast to the baseline results above, the contribution of the term premium in 1999 is clearly underestimated in a model without macro factors. The same goes for the average expected path in 2007-2008. Therefore, this discrepancy illustrates again the necessary inclusion of unspanned macro factors. Even though the NCVAR-based model (averaging estimator with unspanned macro factors) is preferable, I also check the results obtained with the VAR-based and CVAR-based contributions of the average expected path of the short rate and of the term premium.<sup>19</sup> The overall qualitative results are similar though, as expected, slight differences exist because of the nature of the underlying models. For instance, the average expected path of the short rate ( $Exp_t^{5Y}$ ) displays a somewhat more significant contribution under the CVAR-based model, which is mainly due to its higher volatility as we saw with Figure 5 while its contribution is clearly weaker under the VAR setting, thus exaggerating the role of the term premium. All in all, these additional results confirm

<sup>18</sup>Figures are provided in Appendix D

<sup>19</sup>Figures are provided in Appendix D

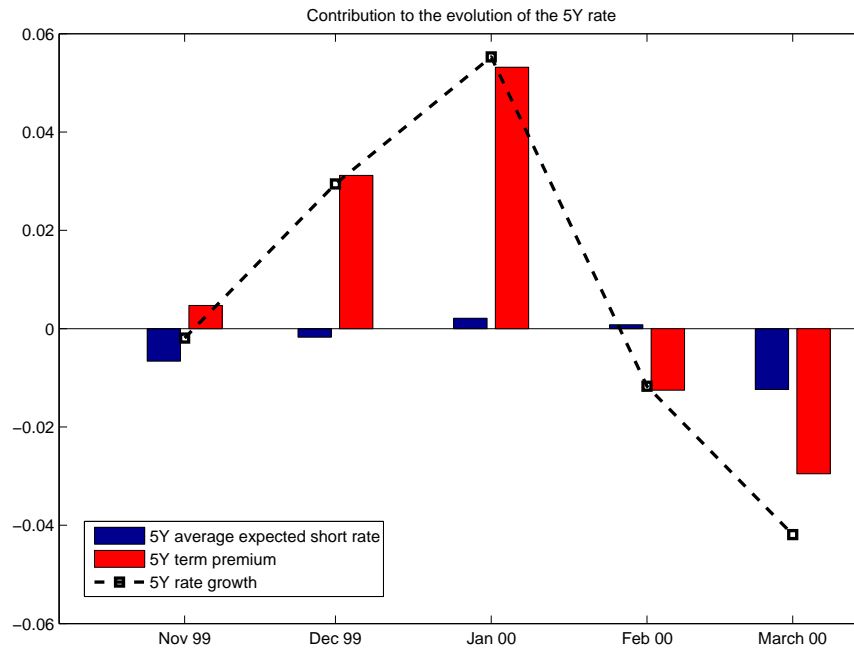

Figure 9: Contribution of  $Exp_t^{5Y}$  (in blue, left bar) and of  $YTP_t^{5Y}$  (in red, right bar) to the evolution of the 5-year bond yield (black dashed line) from November 1999 to March 2000.

the relevance of the averaging-estimator-based term structure model when studying the "Greenspan conundrum".

From the perspective of monetary policy, under the standard EH framework, the only way for the central bank to control long-term yields is by influencing market expectations of future monetary policy. The results presented here show that long bond yields do not always mechanically follow the short rate and its expected average path. However, under the extended framework of the EH, I find that long-term risk-free yields in the Euro area are buffered by a substantial and time-varying term premium. Thus the central bank not only has to guide market expectations of its future policy but it also has to take measures to alter this risk premium. The selected conundra highlighted here illustrate the difficulties faced by central banks in guiding market expectations as well as in influencing the term premium. On that point, problems in the adequation between the supply and demand of sovereign bonds (due to several structural factors as mentioned in Kim and Wright (2005)) likely drove the term premium downward in the European bond market.

## 8 Conclusion

Central banks attempt to influence the movements of the sovereign yield curve. Unfortunately, the task is not without difficulties. The Expectation Hypothesis emphasizes the decisive role of

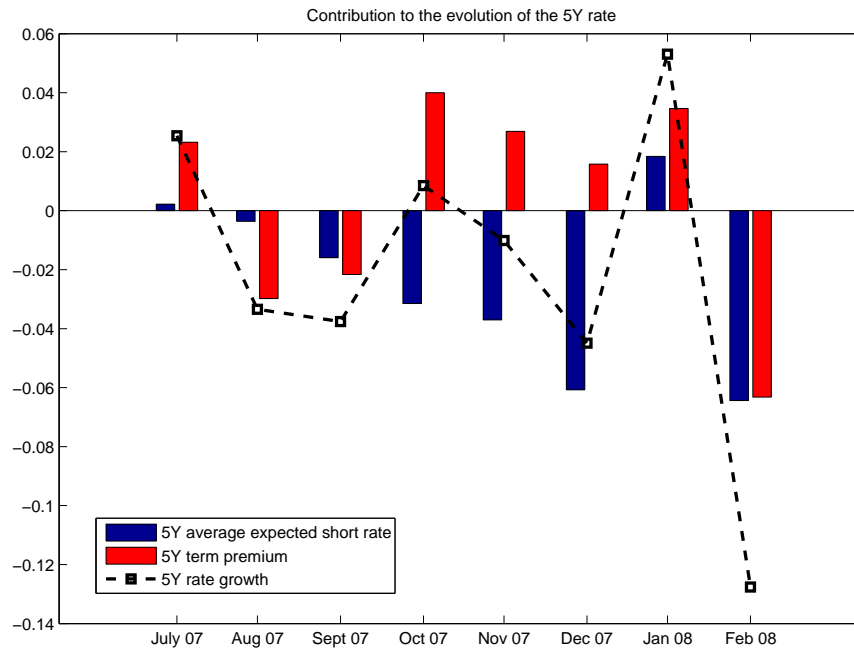

Figure 10: Contribution of  $Exp_t^{5Y}$  (in blue, left bar) and of  $YTP_t^{5Y}$  (in red, right bar) to the evolution of the 5-year bond yield (black dashed line) from June 2007 to January 2008.

short rate expectations in determining long-term interest rates. But deviations from the hypothesis primarily stem from investors' risk aversion, who therefore demand a risk premium.

In this paper, I estimate an arbitrage-free Gaussian term structure model for the Euro area which allows for macro risks to be priced distinctly from the yield curve. Indeed, the state factors of the model include macroeconomic variables which are not entirely spanned by bond yields. I also adopt a relevant estimation approach which yields better term premium estimates than a conventional unconstrained VAR model by using averaging estimators. The estimated term structure is consistent with the Euro area, as unspanned macro risks are taken into account in line with the observed data. Moreover, the econometric methodology used provides more accurate estimates of long-horizon term premium.

In parallel with past studies on the US bond market, the present analysis shows that the Eurozone went through its own "Greenspan conundra". In contrast with what would have been predicted according to the Expectation Hypothesis, unexpected movements during the last tightening episodes occurred on the long end of the yield curve. The estimated affine term structure model emphasizes the contribution of the long term premium to the "conundra" in 2000 and 2004-2005, which is similar to the US case. However, the results highlighted here do not always picture it as being the sole factor behind the bond conundra. Market expectations of the ECB's future monetary policy as well as the term premium both contribute to the difficulties faced by the central bank to impact long-term yields towards a direction it sees fit.

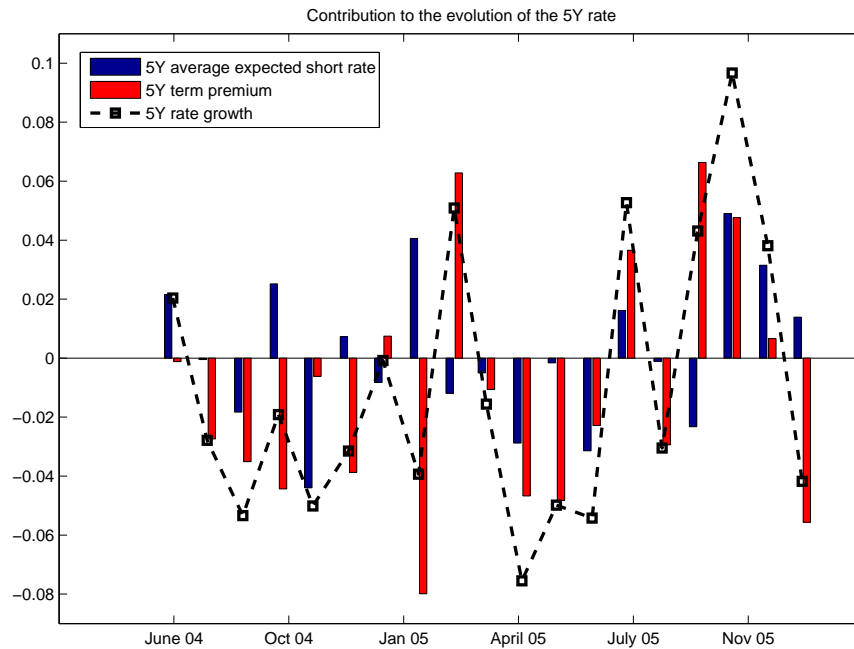

Figure 11: Contribution of  $Exp_t^{5Y}$  (in blue, left bar) and of  $YTP_t^{5Y}$  (in red, right bar) to the evolution of the 5-year bond yield (black dashed line) from June 2004 to December 2005.

## A Appendix: Modeling the yield curve

### A.1 Brief reminder

The yield curve is the center of interest for macroeconomists, financial economists and practitioners alike.

On the one hand, in the case of macroeconomists, the goal was mostly to assess the impact of various shocks on the yield curve. A first natural approach is the one chosen by ? or Evans and Marshall (1998, 2007) which mainly consists in a unrestricted VAR estimated for a set of yields. Indeed, they include both macroeconomic variables and bond yields of various maturities in a standard VAR process in order to see for instance how exogenous impulses to monetary policy affect bond yields of various maturities. One central drawback of these simple macro models lies in the relatively large number of coefficients to be estimated if we want to consider a broad range of yield maturities. Results might also depend on the set of yields chosen. However, their most critical weakness is that they can allow arbitrage opportunities, i.e. investors can devise a riskless and profitable strategy which consists in buying a long-term zero-coupon bond and selling some combinations of the others in the model.

On the other hand, in the empirical finance literature, macroeconomic linkages are simply ignored and the entire set of bond yields is explained by a few latent factors while taking into account the no-arbitrage restriction. Models developed by Duffie and Kan (1996) and Dai and Singleton (2000) are representative of this class and provide an excellent fit. The factors underlying bond yields have actually no direct economic meaning and do not provide any clue on the macroeconomic forces behind the movements of the yield curve. However, the no-arbitrage restriction enforces the consistency of evolution of the yield curve over time with the absence of arbitrage opportunities. The main drawback of arbitrage-based term structure models is that they have little to say about the dynamics of interest rates as their primary concern is to fit the curve at one point in time and cannot be used for forecasting.

A seminal paper by Ang and Piazzesi (2003) was the first to bridge the gap between these two worlds. They introduce a no-arbitrage term structure model based on the assumption that the short rate depends on some yield-related latent factors and two macroeconomic variables (inflation and a real activity indicator) as with a simple Taylor rule. Their model became the backbone of many macro-finance affine term structure models.

### A.2 The framework of the term structure model

#### A.2.1 The stochastic discount factor

Following ?, the no-arbitrage restriction implies there exists a strictly positive random variable,  $m_{t+1}$ , called the stochastic discount factor (SDF for short). The SDF simply extends the ordinary discount factor found for example in corporate finance textbook to an environment with uncertainty and risk-averse agents. All assets in the economy are then priced according to the following equation:

$$P_t = \mathbb{E}_t^{\mathbb{P}} [m_{t+1} P_{t+1}] \quad (23)$$

where  $P_t$  denotes the price of a given asset,  $m_{t+1}$  is the discount factor used to value the state-contingent payoff of the asset at time  $t + 1$  and  $\mathbb{P}$  denotes the historical probability measure. In particular, the price  $p_t^n$  of a  $n$ -period zero-coupon bond at time  $t$  which pays only one euro at time  $t + n$  satisfies the following similar equation:

$$p_t^n = \mathbb{E}_t^{\mathbb{P}} [m_{t+1} p_{t+1}^{n-1}] \quad (24)$$

For this zero-coupon bond, only one payment (of 1 euro) is supposed to be made to the bearer at maturity time  $t + n$ . Therefore, at time  $t + n - 1$ , Equation (24) becomes:

$$p_{t+n-1}^1 = \mathbb{E}_{t+n-1}^{\mathbb{P}} [m_{t+n}] \quad (25)$$

By successive backward iterations and with the law of iterated expectations, the  $n$ -period zero-coupon bond price at time  $t$  is:

$$p_t^n = \mathbb{E}_t^{\mathbb{P}} \left[ \prod_{i=1}^n m_{t+i} \right] \quad (26)$$

Equation (23) and (24) reflect the no-arbitrage restriction imposed on the various bonds. To see why that restriction is actually enforced in these equations, we can consider a simple framework in which  $m_t = m = \frac{1}{1+r}$  ( $r$  being the risk-free rate) and a one-period zero-coupon bond of price  $p_t^1$  at time  $t$ . Suppose equation 25 doesn't hold, that is,  $p_t^1 < m \times 1$  as a first example. In such case, an investor can borrow  $p_t^1$  at time  $t$  at the riskless rate  $r$ , buy the zero-coupon bond. Her total profit would be  $1 - p_t^1/m > 0$  which would amount to a perfect arbitrage. The same goes for the assumption  $p_t^1 > m \times 1$ . Thus, (23) and (24) must hold. The no-arbitrage restriction actually constrains the way bond yields can move relative to one another.

Let  $y_t^n = -\log(p_t^n)/n$  denotes the yield of the  $n$ -period zero-coupon bond.

I then assume that  $(m_{t+1})$  can be written as:

$$m_{t+1} = e^{-r_t} \frac{\xi_{t+1}}{\xi_t} = \exp \left( -r_t - \frac{1}{2} \lambda_t' \lambda_t - \lambda_t' \varepsilon_{Z_{t+1}}^{\mathbb{P}} \right) \quad (27)$$

where  $r_t$  is the short rate,  $\xi_{t+1}$  follows a conditional log-normal process and  $\lambda_t$  is the time-varying market prices of risk associated with the source of uncertainty  $\varepsilon_{Z_t}^{\mathbb{P}}$ , being i.i.d. normal with  $\mathbb{E}[\varepsilon_{Z_t}^{\mathbb{P}}] = 0$  and  $Var[\varepsilon_{Z_t}^{\mathbb{P}}] = I$ . If risk neutrality were to hold, Equation (27) would simply reduce to  $m_{t+1} = e^{-r_t}$ . Subsequently, Equation (26) would become  $p_t^n = \mathbb{E}_t^{\mathbb{P}} \left[ \exp \left( -\sum_{i=0}^{n-1} r_{t+i} \right) \right]$ . In terms of bond yields, this relationship is equivalent to  $y_t^n = \frac{1}{n} \sum_{i=0}^{n-1} r_{t+i}$ , i.e. the Expectation Hypothesis actually holds if risk aversion is supposed to be absent in the model.

### A.2.2 Bond pricing with the SDF

Assume the short rate and the market prices of risks linearly depend on some factors  $Z_t$  so that

$$\begin{cases} r_t = \rho_0 + \rho_1 Z_t \\ \lambda_t = \lambda_0 + \lambda_1 Z_t \end{cases} \quad (28)$$

Suppose the factors  $Z_t$  follow under the historical measure the dynamic below:

$$\Delta Z_t = K_{0Z}^{\mathbb{P}} + K_{1Z}^{\mathbb{P}} Z_{t-1} + \Sigma_Z \varepsilon_{Z_t}^{\mathbb{P}} \quad (29)$$

Using (24), (27), (28) and (29), it can be shown that  $p_t^n = \exp(\overline{A}_n + \overline{B}_n' Z_t)$  with  $(\overline{A}_n, \overline{B}_n)$  both satisfying the following recursive equations:

$$\begin{cases} \overline{A}_{n+1} = \overline{A}_n + \overline{B}_n' (K_{0Z}^{\mathbb{P}} - \Sigma_Z \lambda_0) + \frac{1}{2} \overline{B}_n' \Sigma_Z \Sigma_Z' \overline{B}_n - \rho_0 \\ \overline{B}_{n+1} = (I + K_{1Z}^{\mathbb{P}} - \Sigma_Z \lambda_1)' \overline{B}_n - \rho_1 \end{cases} \quad (30)$$

The initial conditions are  $\overline{A}_1 = -\rho_0$  and  $\overline{B}_1 = -\rho_1$ .

Bond yields are therefore affine in  $Z_t$ .

When  $\lambda_0 = \lambda_1 = 0$ , investors are then supposed to be risk-neutral. In fact, risk-averse investors actually value any bonds the same way as risk-neutral investors would do if they thought that the state vectors follow an alternative law of motion under a different probability measure  $\mathbb{Q}$ :

$$\Delta Z_t = K_{0Z}^{\mathbb{Q}} + K_{1Z}^{\mathbb{Q}} Z_{t-1} + \Sigma_Z \varepsilon_{Z_t}^{\mathbb{Q}} \quad (31)$$

where  $K_{0Z}^{\mathbb{Q}} = K_{0Z}^{\mathbb{P}} - \Sigma_Z \lambda_0$  and  $K_{1Z}^{\mathbb{Q}} = K_{1Z}^{\mathbb{P}} - \Sigma_Z \lambda_1$ .

Equation (29) is commonly referred to the physical/historical risk representation and (31) as the risk-neutral representation of the law of motion for the state vector ( $\mathbb{P}$  and  $\mathbb{Q}$  respectively). Notice that both laws are identical to each other when  $\lambda_0 = \lambda_1 = 0$ , which is equivalent to the hypothesis of risk-neutral investors.

To estimate the model, one can either specify the set of parameters as  $(\rho_0, \rho_1, K_{0Z}^{\mathbb{P}}, K_{1Z}^{\mathbb{P}}, \lambda_0, \lambda_1, \Sigma_Z)$  or in terms of  $(\rho_0, \rho_1, K_{0Z}^{\mathbb{P}}, K_{1Z}^{\mathbb{P}}, K_{0Z}^{\mathbb{Q}}, K_{1Z}^{\mathbb{Q}}, \Sigma_Z)$ . The first specification applies to everything above. The second one applies to an equivalent framework which will be detailed below. In the latter case, one needs to specify the factors' dynamics under the historical and risk-neutral measure in the model's assumptions.

### A.2.3 Risk-neutral bond pricing

The second specification  $(\rho_0, \rho_1, K_{0Z}^{\mathbb{P}}, K_{1Z}^{\mathbb{P}}, K_{0Z}^{\mathbb{Q}}, K_{1Z}^{\mathbb{Q}}, \Sigma_Z)$  which directly includes risk-neutral parameters actually calls upon another implication of ? for asset pricing, which is purely equivalent to the pricing framework using the SDF. Under the assumption of no arbitrage (with market prices of risk affine in the factors  $Z_t$ ), there exists a risk-neutral probability measure  $\mathbb{Q}$  that is equivalent to the physical measure  $\mathbb{P}$ . Once again, the price of a zero-coupon bond is similar to what was described earlier with the SDF  $m_{t+1}$ , that is:

$$p_t^n = \mathbb{E}_t^{\mathbb{Q}} [\exp(-r_t) p_{t+1}^{n-1}] \quad (32)$$

$$= \mathbb{E}_t^{\mathbb{Q}} \left[ \exp \left( - \sum_{i=0}^{n-1} r_{t+i} \right) \right] \quad (33)$$

Under the risk-neutral measure, the state vectors follow the law of motion:

$$\Delta Z_t = K_{0Z}^{\mathbb{Q}} + K_{1Z}^{\mathbb{Q}} Z_{t-1} + \Sigma_Z \varepsilon_{Z_t}^{\mathbb{Q}} \quad (34)$$

With the definition of the short rate and the risk-neutral dynamics, one can once again write the price of a zero-coupon bond as an exponential affine function of the factors  $Z_t$ :

$$p_t^n = \exp \left( \overline{A}_n + \overline{B}_n' Z_t \right) \quad (35)$$

with  $\overline{A}_n$  and  $\overline{B}_n$  following the recursive equations and initial conditions  $\overline{A}_1 = -\rho_0$  and  $\overline{B}_1 = -\rho_1$ :

$$\begin{cases} \overline{A}_{n+1} = \overline{A}_n + \overline{B}_n' K_{0Z}^{\mathbb{Q}} + \frac{1}{2} \overline{B}_n' \Sigma_Z \Sigma_Z' \overline{B}_n - \rho_0 \\ \overline{B}_{n+1} = (I + K_{1Z}^{\mathbb{Q}})' \overline{B}_n - \rho_1 \end{cases} \quad (36)$$

All in all, both approaches are strictly equivalent but I chose to follow the risk-neutral one in the paper. Therefore, the market prices of risk  $(\lambda_0, \lambda_1)$  are neither explicitly specified nor estimated in my model.

#### A.2.4 A model with unspanned macro factors

In the modified framework, using the risk-neutral measure, the price of a zero-coupon bond (yield respectively) of maturity  $n$  is only an exponential affine (affine respectively) function of the factors  $P_t$ :

$$p_t^n = \exp \left( \overline{A}_n + \overline{B}_n' P_t \right) \quad (37)$$

$$y_t^n = \widetilde{A}_n + \widetilde{B}_n' P_t \quad (38)$$

with  $\overline{A}_1 = -\rho_0$ ,  $\overline{B}_1 = -\rho_1$ .  $\overline{A}_n = -n\widetilde{A}_n$  and  $\overline{B}_n = -n\widetilde{B}_n$  are deduced from the recursive equations below:

$$\overline{A}_{n+1} = \overline{A}_n + \overline{B}_n' (K_{0P}^{\mathbb{Q}}) + \frac{1}{2} \overline{B}_n' \Sigma_P \Sigma_P' \overline{B}_n - \rho_0 \quad (39)$$

$$\overline{B}_{n+1} = (I + K_{1P}^{\mathbb{Q}})' \overline{B}_n - \rho_1 \quad (40)$$
