Elusive Relationship between Business-cycle Volatility and Long-run Growth

Abstract

This paper revisits the empirical relationship between business-cycle volatility and long-run growth. The key contribution lies in controlling for fluctuations in the trend growth that also accounts for enormous heterogeneity among countries in their long-run growth trajectories; otherwise, the estimating equation would be misspecified. We find that there is no effect of BC volatility on growth once estimation duly accounts for these fluctuations. Otherwise, there would be a significant effect of BC volatility on growth that also varies across time period and country income groups. We instead find a negative effect of persistence in volatility on growth. The results have implications in light of recent global financial crises, and also for cross-country regressions.

JEL Classification Codes: E32, F44, O11, O40.

Keywords: Growth, Business cycles, Volatility, Volatility persistence.

Elusive Relationship between Business-cycle Volatility and Long-run Growth

1. Introduction

This paper revisits the empirical relationship between business-cycle (BC) volatility¹ and long-run growth but the key contribution lies in controlling for fluctuations in the trend growth. Addressing these fluctuations also accounts for enormous heterogeneity among countries in their long-run growth trajectories. The main finding is that the significant volatility-growth correlation (or arguably the causal effect of BC volatility on long-run growth) documented in the literature—either negative or positive—disappears after controlling for such fluctuations.

Both the theoretical and empirical literature on the relationship between BC volatility and long-run growth lacks consensus. In the Schumpeterian (1939) tradition, where the mechanism is “creative destruction,” the effect of business cycles on long-run growth is positive. For example, Caballero and Hammour (1994) view recessions are a time of “cleansing,” when outdated or unprofitable techniques and products are pruned out of the productive system. During recessions firms also accumulate “organizational capital” (Hall, 1991) and/or reallocate labor (Davis and Haltiwanger, 1990; 1992) that induce growth in the long run.

In contrast, a negative relationship between BC volatility and long-run growth is predicted by endogenous growth theory based on the idea of learning-by-doing or demand spillovers (Arrow, 1962; Stadler, 1990; Martin and Rogers, 1997). For example, business cycles create fluctuations in employment, and the unemployed lose their skills in recessions. Therefore, in the presence of negative learning-by-doing, temporary shocks have negative impact on long-run growth.² However, in the models based on the opportunity cost arguments, the prediction of the effect of business cycles on growth can be both positive and negative (Aghion and Saint-Paul, 1998). For example, if the cost of productivity improvements positively depends on current production, and this cost drops by more than its present discounted benefit in a recession, then business cycles have a positive effect on growth. Saint-Paul (1997) provides evidence at the

¹ This is volatility of growth rate as opposed to volatility of level of GDP.

² Blackburn (1999) and Blackburn and Pelloni (2004) point out that the negative relationship based on learning-by-doing may not hold in a stochastic growth model.

aggregate level in favor of this argument. On the other hand, if the cost of productivity-enhancing activities does not depend on current production, the conclusion of the model reverses and recession have a negative long-run effect.

Given the lack of consensus on the theoretical predictions, the burden is on the empirical side to establish the actual relationship. But empirical evidence also lacks consensus. For example, Kormendi and Meguire (1985), Grier and Tullock (1989) and Stastny and Zagler (2007) find a positive correlation between business cycles and long-run growth. In contrast, Ramey and Ramey (1995), Martin and Rogers (2000), Kneller and Young (2001), Fatás (2002), Döpke (2004) and Rafferty (2005) find a negative correlation. The observed relationship also varies across country groups. For example, Martin and Rogers (2000) find a negative relationship for the industrialized countries but insignificant relationship for the non-industrialized countries. They attribute learning-by-doing as a mechanism that may not be at work for the latter group of countries.³ Imbs (2007) finds volatility and growth to be positively related at the sectoral level but negatively related at the aggregate level. Furthermore, it has not been established satisfactorily whether the observed relationship is a correlation or a causal effect of BC volatility on long-run growth. It is important to point out that the theoretical models implicitly argue for an effect of BC volatility on future growth, while the empirical studies have tested a contemporaneous correlation or causation.

Notwithstanding a large body of empirical research on the volatility-growth relationship, the literature has categorically ignored fluctuations in the trend growth. The following examples in Table 1 will illuminate the danger of ignoring such fluctuations in estimation. Consider two countries—*A* and *B*—with identical average growth performances over 20 years (for simplicity consider arithmetic average). Suppose that the annual growth rate in country *A* alternated every year between 2% and -2% (i.e., 2, -2, 2, -2, --- 2, and -2), while that in country *B* was 2% in the first 10 years and -2% in the last 10 years. Both countries have the same average growth rate (zero) and volatility (measured by the standard deviation which is 2.052) but patterns of the trend growth in these two countries are clearly different. The trend growth rate in country *B* is seven times as volatile as in country *A* (the standard deviation of the trend growth calculated using the Hodrick-Prescott (H-P) filter is 0.270 and 1.908 in country *A* and *B*, respectively). On the other

³ Young (1993) also argues that growth will be driven by learning-by-doing only at relatively high levels of development.

hand, BC volatility (measured by the standard deviation of the cyclical component calculated using the same filter) in country *A* is 3.5 times as large as in country *B* (2.001 and 0.567, respectively). Suppose, there is another country *C* that experienced a -2% growth rate in the first 12 years, zero in next 2 years and 4% in the last 6 years. Although average growth in country *C* is also zero and its BC volatility (0.573) is similar to that in country *B*, volatility of its trend growth (2.62) is greater than that in both *A* and *B*. In Section 3, we provide similar examples observed in the data.

Insert Table 1 here

The above examples illustrate that many dissimilar growth trajectories that differ in terms of fluctuations in the trend growth can lead to the same average growth rate. By ignoring these fluctuations, the literature also fails to address the enormous heterogeneity among countries. In this paper, we address these fluctuations by the standard deviation of the trend (long-run) growth rate calculated by the low-pass filter (we refer it to long-run (LR) volatility). The reason for controlling LR volatility in estimation can also be understood from the following volatility decomposition. Given that there are enormous transitory (cyclical) variations around the trend growth for many countries and that the trend growth *per se* is also volatile, per capita real GDP growth rate ($g_{y,t}$) can be written as the sum of two orthogonal terms, its business-cycle ($g_{y,t}^{BC}$) and long-run components ($g_{y,t}^{LR}$): $g_{y,t} = g_{y,t}^{BC} + g_{y,t}^{LR}$.⁴ Its variance is then decomposed as

$$\text{Var}(g_{y,t}) = \text{Var}(g_{y,t}^{BC}) + \text{Var}(g_{y,t}^{LR}).$$

We use this spectral relation to explore the volatility-growth relationship at the cross-country level. Our main source of data is the PWT 8.0. We choose the 1960-2007 period because of unavailability of data for the control variables used in the regression analysis for periods earlier than 1960 and to ensure that our results are not influenced by the recent global financial crises that started in 2008. We perform split sample analysis for different sub-periods, and also by disaggregating the sample countries by income groups and their intensity of BC volatility. To

⁴ Romer (2012, p. 136) stresses that statistical tests do not determine whether growth rate is stationary or nonstationary; rather they suggest that “there are highly transitory movements in growth that are large relative to any long-lasting movements that may be present.” The question of stationarity is also economically unimportant.

verify the results from an alternative dataset and different time periods, we perform a separate analysis for the 1875-2010 period using the historical time series compiled by Angus Maddison for a relatively small number of countries. As an additional robustness check, we replicate Ramey and Ramey (1995, AER), the seminal contribution that has initiated the empirical volatility-growth literature, using their data.

The BC and LR volatility are calculated as the standard deviation of the cyclical and long-run components of (annual) per capita real GDP growth rate, respectively. We extract these two components employing the Baxter-King (B-K) (1999) filter at the business-cycle and low frequencies, respectively.⁵ We choose a window of 3 years, and critical periodicities (inversely related to frequencies) of 2 and 8 years for the business cycle, and 8 years and above for the long-run. Our regression analyses are based on both cross-section and panel data. The cross-section data is constructed by taking average and calculating standard deviation of the relevant variables over the entire sample period. To construct the panel data, non-overlapping average over 7 years has been taken for the annual growth rate and other series. In Section 2 (and Appendix A.1), we show that averaging over 7 years performs better in terms of reweighting the variances of the raw series across low frequencies than averaging over 5 years as commonly done in the cross-country growth literature. BC and LR volatility have been calculated as the standard deviation of the respective filtered growth rates over the same interval.

We test both the causal effect of BC volatility on growth as well as their correlation. Furthermore, we test the theoretical prediction of the causal effect of BC volatility in the previous period on current growth that has been neglected in the empirical literature. Our empirical strategy is standard in that growth rate is regressed on BC volatility and a set of conditioning variables but departs from the existing literature by additionally controlling for LR volatility. Our main argument is that omitting LR volatility causes misspecification of the regression equation thus leading to wrong inferences about the true relationship. The conditioning variables have been chosen so as to address other omitted variables in the regression equation. Construction of BC and LR volatility using the filtered data generates reverse causality in the panel data. The B-K filter transforms the data using a two-sided symmetric moving average of both lead and lag values; therefore, both BC and LR volatility

⁵ Baxter and King (1999, p. 587) discuss the advantage of calculating BC volatility using their band-pass filter over other methods.

estimated for a particular interval (τ) incorporate growth data in the forward ($\tau + 1$) interval, thus generating reverse causality in the regression of average growth on BC and LR volatility. To address this source of endogeneity, our instruments are respective standard deviation of band- and low-pass filtered growth series constructed by modifying the filter as one-sided using only lag values. Although standard in the literature, standard deviation may not represent the true volatility, and thus may be measured with errors. To account for the endogeneity of BC (LR) volatility due to measurement errors, we order countries by their BC (LR) volatility and employ this ordering score (i.e., ranking of countries) as the instrument, which is based on the assumption that measurement errors do not vary in a way so as to alter the distribution of countries in terms of their BC (LR) volatility (detail discussions on identification in Section 4.2).

We find that there is no correlation between BC volatility and growth after correcting the misspecification. There is also no effect of BC volatility, either current or lagged, on growth. The result is robust in all datasets. But in the misspecified equation that omits LR volatility, both the correlation and causal effect become significantly negative, especially for developing countries. There is a positive effect of BC volatility for developed countries but that is not robust across time periods. The direction of bias in the coefficient on BC volatility depends on the correlation between growth rate and LR volatility omitted in the regression. Our measure of LR volatility can also be interpreted as persistence in volatility. We instead find that persistence in volatility has a negative effect on growth in general and for developing countries in particular.

Our results have important implications in light of the recent global financial crises that caused a prolonged recession and depressed many developed economies enough to lower their trend growth. However, such contractions are more frequent in developing than developed countries. Berg, Ostry and Zettelmeyer (2012) show that inequality of the income distribution, lack of democratic institutions and macroeconomic instability are some factors that cause shorter growth spells (prolonged and more frequent recessions). Mallick (2014) shows that terms-of-trade volatility and financial underdevelopment cause persistent growth volatility. But these characteristics may also be symptoms as well as propagation mechanisms of volatility persistence. Understanding volatility persistence is crucial for designing stabilization policies but this is an under-researched area, even in the context of developed countries.

The rest of the paper proceeds as follows. Section 2 discusses the data including construction of both BC and LR volatility. Section 3 motivates the paper by presenting examples

of heterogeneity observed among countries in terms of their growth trajectories. This section also presents some key descriptive statistics. The estimation strategy and identification are explained in Section 4. The results are discussed in Section 5. Section 6 compares the relative importance of volatility and its persistence in explaining growth. Section 7 compares this paper's contribution in the cross-country macroeconomic literature regarding volatility persistence. Finally, Section 8 concludes.

2. Data

In this section we explain the data used in our empirical analysis including construction of BC and LR volatility.

The main source of data is the PWT 8.0. Average per capita growth rate and volatility have been calculated from the RGDP^{NA} series (the real GDP at constant national prices), which is recommended to compare growth rates across time and countries (Feenstra, Inklaar and Timmer, 2013, Table 5 in p. 30). Per capita real GDP (Y) is calculated by dividing RGDP^{NA} by population (POP). Annual growth rate is calculated as the log difference: $dy_t = \ln(Y_t / Y_{t-1})$.

The BC and LR volatility have been calculated as the standard deviation of the cyclical and long-run components of dy_t , respectively, extracted employing the B-K filter.⁶ A window of 3 years, and critical periodicities of 2 and 8 years for cyclical components (band-pass filter), and 8 years and above for long-run components or equivalently low frequency components (low-pass filter) have been chosen.⁷ The main purpose of a filter is to extract the cyclical components of a

⁶ Levy and Dezhbakhsh (2003) and Mallick (2014) calculate BC and LR volatility using the spectral method by integrating the spectrum over the relevant frequency ranges. However, this method requires relatively long time series, so that it cannot be employed in our panel data analysis. Fatás (2000a, 2000b), Levy and Dezhbakhsh (2003), Aguiar and Gopinath (2007) and Nakamura, Sergeyev and Steinsson (2012) employ the Cochrane's (1988) variance ratio to calculate LR volatility but this method cannot be used to calculate BC volatility. Another alternative can be unobserved component model (UCM). For example, Stock and Watson (2007) and Ascari and Sbordone (2014) estimate the time varying volatility of the trend and cyclical components of inflation for the USA. The UCM is not suitable at the cross-country level because it requires assumptions about the specification of the components.

⁷ Comin and Gertler (2006), Comin (2009) and Comin et al. (2014) employ a non-standard definition of long-run in terms of the periodicity of 200 quarters and above. They refer to the periodicities between 2 and 200 quarters as the medium-term business cycle of which periodicities between 2 and 32 quarters as the high-frequency component of

series, and the long-run components are then recovered as the residual. We instead extract the long-run components using the low-pass filter assuming that per capita real GDP growth is stationary.

Average growth rate (g_y) is the time average of dy_t . For the cross-section data, we take average of dy_t and calculate the standard deviation of the filtered series over the entire sample period. The panel data have been constructed by non-overlapping averaging over 7 years. A common practice is to take a 5-year non-overlapping average of annual growth rate to calculate its long-run value (some papers also take a 10-year average for robustness check). Using the spectral density, we show in Appendix A.1 that data averaged over 5-year period does not reweight the variances of the raw series enough across low frequencies, thus data are contaminated by high frequencies. This contamination decreases substantially in the case of 7-year averaging. Further improvement is small for averaging over longer horizon, such as 8 or 10 years. Since averaging over longer horizon leaves fewer observations for estimation, we choose 7 years as an optimal compromise.

For initial level of GDP, we use the CGDP^e series (expenditure-side real GDP at current PPPs in million 2005 US\$ that compares relative living standards across countries at a single point in time), as recommended by Feenstra, Inklaar and Timmer (2013, Table 5 in p. 30). Terms of trade (ToT) is calculated as the ratio of export to import price (PL_X / PL_M). Investment and government expenditure shares of GDP are the CSH_I and CSH_G series, respectively.

Openness is the sum of exports and imports as a share of GDP at the current price and the data are obtained from the PWT 7.1 (these data are not available in the PWT 8.0). Educational attainment data are from the Barro-Lee (2013) dataset. Political violence is captured by the total summed magnitudes of all societal and interstate major episodes of political violence (MEPV) in

the medium-term (the standard business cycles), and frequencies between 32 and 200 quarters as the medium-frequency component of the medium-term. The authors also show that high and medium term fluctuations of GDP are connected. Our definition of long-run periodicities of 8 years (32 quarters) and above includes their medium-frequency components, and we emphasize the importance of correlation between growth volatility at business cycle and long-run periodicities. Chirinko and Mallick (2014) demonstrate in a different context that a critical periodicity of 8 years sufficiently captures the long-run information, and gain from further increasing this cut-off is negligible.

a country compiled by Center for Systemic Peace.⁸ Private credit data have been collected from Financial Development and Structure Dataset compiled by Beck et al. (2000) and revised by Čihák et al. (2012).

3. Heterogeneous growth trajectories: Some examples

In the introduction, we motivated by a hypothetical example about possible heterogeneity among countries in their growth trajectories. In this section, we provide several examples of such heterogeneity observed in the data in terms of growth rate, BC volatility and LR volatility for 1960-2007 period. Detail information for all sample countries is provided in Appendix A.2. We also discuss some descriptive statistics at the end of this section.

Namibia vs. Nepal: These two developing countries had the same average growth rate (about 0.013) and BC volatility (0.026), but LR volatility in Namibia was about twice as large as in Nepal (0.019 and 0.010, respectively).

Columbia vs. Australia: Both countries had almost the same average growth (0.020 vs. 0.021) and BC volatility (0.015 vs. 0.014), but LR volatility in Columbia was much larger than in Australia (0.013 and 0.008, respectively). This comparison is between a developing and a developed country.

Argentina vs. Burkina Faso: These two countries also differ only by their LR volatility (0.022 vs. 0.014); otherwise, they are similar in terms of average growth (about 0.011) and BC volatility (about 0.044).

Romania vs. Malaysia: Both countries had the same average growth (0.041). But BC volatility was larger in Malaysia (0.033) than in Romania (0.026), while Romania (0.044) had more than twice as large LR volatility as Malaysia (0.020).

⁸ MEPV is an annual, cross-national, time-series data on interstate, societal, and communal warfare magnitude scores (independence, interstate, ethnic, and civil violence and warfare) for all countries. We use the ACTOTAL series in the dataset. ACTOTAL is calculated as the sum of the magnitude score of episode(s) of: i) international violence, ii) international warfare, iii) civil violence, iv) civil warfare, v) ethnic violence, and vi) ethnic warfare involving that state in that year. Each type of violence/warfare is scaled from 1 (lowest) to 10 (highest) for each MEPV (magnitude scores for multiple MEPV are summed with 0 denoting no episodes).

Japan vs. Cyprus: Both countries had the same average growth (0.043). However, compared to Cyprus, Japan experienced milder BC volatility (0.033 vs. 0.056) but greater LR volatility (0.036 vs. 0.020).

Mauritania vs. Fiji: Both countries experienced the same average growth (0.018) but Mauritania had much greater BC volatility (0.064 vs. 0.043) as well as LR volatility (0.039 vs. 0.017) than Fiji.

Israel vs. Egypt: The two neighbors experienced similar average growth (0.034 vs. 0.037) but Israel had greater BC volatility (0.053 vs. 0.032) as well as LR volatility (0.036 vs. 0.015) than Egypt.

Such heterogeneity is also present among developed countries. For example, for the 1970-2007 period, average growth rate and BC volatility were the same at 0.024 and 0.014, respectively, both in Japan and Austria, but LR volatility was more than twice in Japan (0.014) than in Austria (0.06).

On the other hand, there are examples in which countries with very different average growth rates experienced similar fluctuations. For example, growth rate was much higher in Hong Kong (0.048) than in Bangladesh (0.011) although both countries had the same BC volatility (0.035) and LR volatility (0.019). Niger and Cyprus can be another likely pair. Both countries had very similar BC volatility (0.054 vs. 0.056) and LR volatility (0.025 vs. 0.020), but Niger economy declined at an average rate of 0.012, while Cyprus grew rapidly at the rate of 0.043.

The above examples illustrate an enormous heterogeneity among countries in their growth trajectories. More specifically, very dissimilar growth trajectories can lead to the same average growth. On the other hand, apparently similar growth trajectories can also lead to different average growth. The heterogeneity can also be visualized in Figures 1(a)-(j) that display growth trajectories of the country pairs mentioned above in terms of their long-run growth rate.

Insert Figures 1-3 and Table 2 here

Average growth rate, BC volatility and LR volatility for the 1960-2007 period in a sample of 107 countries⁹ are summarized in Table 2. Countries are classified as high, middle and low income following the World Bank classification. BC volatility decreases with income level—it is 0.046 in low income countries compared to 0.036 and 0.024 in middle (upper and lower middle income combined) and high income countries, respectively. LR volatility is same in both low and middle income countries (around 0.023) and slightly smaller in high income countries (0.020). Figures 2(a)-(b) display that both BC and LR volatility decrease with initial income level. Although BC volatility is larger than LR volatility for all income groups, the ratio of BC volatility to LR volatility is the largest for low income countries followed by middle and high income countries (column (4)). The correlation between BC and LR volatility along with the 95% confidence intervals are reported in column (5). The correlation is 0.61 for all sample countries; it is the largest for high income countries at 0.84 followed by middle and low income countries (0.60 and 0.45, respectively). Figure 3 confirms the positive relationship between BC and LR volatility.

However, there is no definite pattern across regions. For example, both BC and LR volatility are similar in Asia Pacific and Latin America—the two regions that experienced crises in the 1980s-90s—but the average growth rate is almost double in the former than in the latter region. Sub Saharan Africa is the most volatile region. Although Europe is the least volatile region, the ratio of BC to LR volatility in Europe is almost the same as in Latin America. The correlation between the two volatilities is not statistically different from zero except for Sub Saharan Africa. (Other regions cannot be compared because of very small number of sample countries).

4. Estimation strategies

In this section, we discuss the regression specification and the identification strategy we employ to uncover the volatility-growth relationship.

⁹ These 107 countries are based on the availability of RGDP^{NA} data without any discontinuity. Among them, six countries (Equatorial Guinea, Iran, Rwanda, Gabon, Guinea-Bissau and Syria) may be possible outliers based on large BC and LR volatility (Appendix A.2) but we do not exclude them from the sample. The descriptive statistics and regression results do not qualitatively change if these countries are excluded from the sample.

4.1 Estimating equation

Our estimation strategy is based on a regression of long-run growth on BC volatility and a set of conditioning variables including LR volatility. The cross-sectional specifications are given by:

$$g_y = \alpha + \gamma_{1C} BCvol_i + \gamma_2 LRvol_i + \beta y_{i,0} + \mathbf{X}'_i \boldsymbol{\delta} + v_i, \quad \text{---(1a)}$$

$$g_y = \alpha + \gamma_{1U} BCvol_i + \beta y_{i,0} + \mathbf{X}'_i \boldsymbol{\delta} + u_i. \quad \text{---(1b)}$$

Here g_y is the average growth rate of real per capita GDP, $y_{i,0}$ is the log of real per capita GDP in the initial period and \mathbf{X} is a set of conditioning variables. Our attention is on γ_{1C} , the (corrected or credible) coefficient on BC volatility ($BCvol_i$), in equation (1a). We also estimate γ_{1U} (the uncorrected coefficient) in the misspecified equation (1b) without controlling for LR volatility ($LRvol_i$) to get an idea about how the misspecification can lead to wrong inferences about the true relationship. We show the direction of bias in γ_{1U} at the end of this section.

Choice of controls (\mathbf{X}) in cross-country growth regressions is a difficult task given that a large number of variables have been found to be significant in different studies. Some studies control the variables that are robustly significant in extreme bound analysis (or Bayesian model averaging). We take a different approach in order to avert the omitted variable bias that involves carefully controlling only those determinants of growth that also affect BC volatility. Omission of other controls will not cause any bias as long as they are uncorrelated with BC volatility.

The following variables are included in \mathbf{X} : (i) investment share in GDP, (ii) (initial) human capital measured by the year of schooling for aged over 15 years, (iii) population growth rate, (iv) trade openness measured by the sum of exports and imports as a percentage of GDP, (v) growth rate of government share in GDP, (vi) terms of trade (ToT) volatility measured as the standard deviation of the ratio of the export to import prices (as a proxy for external shocks), (vii) political violence (explained in Section 2 and footnote 8), and (ix) financial development proxied by the credit disbursed to the private sector by banks and other financial institutions relative to GDP. Initial (log) per capita income is also included to account for conditional convergence and the transitional dynamics so as to avert a positive bias on the coefficient on BC volatility (for a discussion on the bias, see Martin and Rogers, 2000, p. 365). The variables (i)-(iii) (along with initial income) are the most common controls in growth-volatility regressions

(including Ramey and Ramey, 1995). Investment is crucial for economic growth but it is also the most volatile component of GDP over business cycles. Higher population growth can cause economic (and political) instability in a country unless accompanied by economic growth faster enough to reduce unemployment.¹⁰ Higher human capital, although plays an important role in economic growth, also cause economic and political instability if left unutilized—the recent Arab Spring is a prime example (Kuhn, 2012).

The role of openness in economic growth is established both theoretically and empirically but openness also affects volatility. Using an industry-level panel dataset of manufacturing production and trade, Giovanni and Levchenko (2009) document a positive and economically significant relationship between trade openness and overall volatility. Mallick (2014) also observes similar effects using aggregate data at the cross-country level. Kose, Prasad and Terrones (2006) find out that openness stimulates both growth and volatility. Growth of the share in government expenditure is intended to account for government expenditure shocks documented in the Real Business Cycle literature.

Easterly et al. (1993) document that shocks, measured by the change in the ToT, influence growth directly and also indirectly through policy variables. A negative robust impact of the change in the ToT on growth volatility is documented by Mallick (2014) and Agénor et al. (2000). Mendoza (1995) quantifies ToT shocks as accounting for 40%-60% of the observed variability of GDP at the cross-country level. Koren and Tenreyro (2007) find strong negative correlations between growth and volatility of country level macro shocks.

Rodrick (1999) shows that domestic social conflicts are a key to understanding lack of persistence in growth performance and growth collapse since the mid-1970s. Social conflicts interact with external shocks and the domestic institutions of conflict-management. Acemoglu et al. (2003) argue that bad macroeconomic policies that increase volatility and lower growth are the results of weak institutions, which is also related to social and political instability.¹¹ Ploeg

¹⁰ Higher population growth has also been found to be related to higher consumption volatility (Bekaert, Harvey and Lundblad, 2006).

¹¹ We believe that our measure of political violence, to a large extent, captures the institutional development. Nonetheless, we also additionally control for *Polity2* to verify robustness, especially for developing countries.

and Poelhekke (2009) show that ethnic tensions cause higher volatility and lower growth.¹² Financial development is one of the main channels through which volatility affects growth (Aghion and Banerjee, 2005).

The above list of variables is certainly not a complete one. There may be other factors that trigger both growth and BC volatility. It is conceivable that many omitted variables are related to the level of economic development, and therefore controlling for initial income level in the regression, to a large extent, captures these omitted variables. We additionally include region dummies (Latin America, Sub-Saharan Africa, Asia Pacific, and Middle East and North Africa) in the regression as some regions are more volatile than others for reasons not discussed above; these dummies also capture omitted variables in growth regressions (Berg, Ostry and Zettelmeyer, 2012). Finally, we include dummies for legal origins and landlocked to account for country fixed effects as well as omitted variables. For example, La Porta et al. (1997; 2008) document that financial development of a country is greatly influenced by its legal origin. Financial development data is not available for many (developing) countries before 1980. Therefore, in our specification that excludes financial development, legal origin dummies act as proxies. Growth performance of landlocked countries is dismal and these countries also experience greater volatility as a result of lack of access to the market (Malik and Temple, 2009).

We construct three cross-sectional datasets—for the 1960-2007 full sample period and for the 1960-1980 and 1980-2007 sub-periods—to verify stability of the results across different time periods and sample countries (fewer countries are retained in the full 1960-2007 period because of unavailability of data for some control variables). In addition, we estimate for the 1970-2007 period to capture the immediate effect on volatility of the first global oil price shocks.

The cross-sectional estimation captures the “between” country variations. The panel data allows a richer investigation by also capturing the “within” country variations. The respective estimating equations are written as:

$$g_{y,\tau} = \alpha + \gamma_{1C} BCvol_{i,\tau} + \gamma_2 LRvol_{i,\tau} + \beta_1 y_{i,\tau_0} + \mathbf{X}'_{i,\tau-1} \boldsymbol{\delta} + \mu_i + \eta_\tau + v_{i,\tau}, \quad \text{---(2a)}$$

$$g_{y,\tau} = \alpha + \gamma_{1U} BCvol_{i,\tau} + \beta_1 y_{i,\tau_0} + \mathbf{X}'_{i,\tau-1} \boldsymbol{\delta} + \mu_i + \eta_\tau + u_{i,\tau}. \quad \text{---(2b)}$$

¹² In investigating the effect of uncertainty on growth, Baker and Bloom (2013) used natural disasters, terrorist attacks and unexpected political shocks as instruments of uncertainty measured by the first and second moments of the stock prices. However, the authors recognize the endogeneity of these shocks in the long run.

Here, μ_i is the country fixed effects, η_τ is the aggregate time effects captured by time (interval) dummies and y_{i,τ_0} is the log of real per capita GDP in the initial year of each interval. All control variables are lagged by one period ($\mathbf{X}_{i,\tau-1}$), so that they are treated as predetermined.

Finally, we test the theoretical predictions of the effect of BC volatility in the previous period on current growth by the lagged volatility in the regression. The specification is the same as equations (2) except that BC and LR volatility are lagged one period.

$$g_{y,\tau} = \alpha + \gamma_{1C} BCvol_{i,\tau-1} + \gamma_2 LRvol_{i,\tau-1} + \beta_1 y_{i,\tau_0} + \mathbf{X}'_{i,\tau-1} \boldsymbol{\delta} + \mu_i + \eta_\tau + v_{i,\tau}, \quad \text{---(3a)}$$

$$g_{y,\tau} = \alpha + \gamma_{1U} BCvol_{i,\tau-1} + \beta_1 y_{i,\tau_0} + \mathbf{X}'_{i,\tau-1} \boldsymbol{\delta} + \mu_i + \eta_\tau + u_{i,\tau}. \quad \text{---(3b)}$$

To verify our results from an alternative dataset and time horizon, we estimate the correlation (both contemporaneous and lagged) using the historical data constructed by Angus Maddison. We choose the 1875-2010 period in order to retain a relatively large number of countries in the sample. A 7-year panel data similar to the PWT data has been constructed. We control only for the (log) initial per capita GDP, time (interval) dummies and dummies for the pre-1914, 1914-1945, 1946-1985; and post-1985 periods,¹³ as other controls are not available for such a long period.

It is straightforward to show the direction of bias in the coefficient on BC volatility due to misspecification. To see it, simplify equations (1a)-(1b) excluding the controls:

$$g_y = \alpha + \gamma_{1C} BCvol_i + \gamma_2 LRvol_i + v_i, \quad \text{---(4a)}$$

$$g_y = \alpha + \gamma_{1U} BCvol_i + u_i. \quad \text{---(4b)}$$

The estimated coefficient on BC volatility in equations (4a) and (4b) can be expressed, respectively, as:

¹³ Romer (2012, p. 192) suggested that macroeconomic history of the USA since the late 1800s consists of four broad periods: i) before the Great Depression, ii) the Great Depression and World War II, iii) at the end of the World War II to about mid-1980s, and iv) after mid-1980s. This classification can be generalized to other sample countries except for the first period due to the World War I because most sample countries are from Europe. Therefore, we modify the first period accordingly.

$$\hat{\gamma}_{1C} = \frac{\text{corr}(g_y, BCvol) - \text{corr}(g_y, LRvol) * \text{corr}(BCvol, LRvol)}{1 - [\text{corr}(BCvol, LRvol)]^2} * \frac{\text{Var}(g_y)}{\text{Var}(BCvol)}, \quad \text{---(5a)}$$

$$\text{and } \hat{\gamma}_{1U} = \text{corr}(g_y, BCvol) * \frac{\text{Var}(g_y)}{\text{Var}(BCvol)}. \quad \text{---(5b)}$$

In the data, $\text{corr}(BCvol, LRvol) > 0$. Therefore, the direction of bias in $\hat{\gamma}_{1U}$ in equation (4b) depends on the sign of $\text{corr}(g_y, LRvol)$ or, equivalently, the sign of γ_2 in equation (4a). If $\gamma_2 < 0$, $\hat{\gamma}_{1U}$ will be biased downward (i.e., if $\hat{\gamma}_{1C}$ is positive, $\hat{\gamma}_{1U}$ will move towards 0 (or even can become negative); if $\hat{\gamma}_{1C}$ is negative, $\hat{\gamma}_{1U}$ will increase in absolute value with the negative sign). Similarly, $\gamma_2 > 0$, $\hat{\gamma}_{1U}$ will be biased upward (i.e., if $\hat{\gamma}_{1C}$ is positive, $\hat{\gamma}_{1U}$ will be larger; if $\hat{\gamma}_{1C}$ is negative, $\hat{\gamma}_{1U}$ will move towards 0). Even if $\gamma_2 = 0$, $\hat{\gamma}_{1U}$ will still be biased upward because of $\text{corr}(BCvol, LRvol) > 0$ (in the denominator in equation (5a)).

4.2 Identification

To estimate a casual effect of BC volatility on growth, we need to correct the endogeneity of BC (and LR) volatility.¹⁴ Provided that the omitted variable bias is satisfactorily addressed in the specifications containing LR volatility (Equations 1(a), 2(a) and 3(a)), the remaining source of endogeneity is the reverse causality from growth to volatility. For example, poor growth performance in an economy (at time or interval τ) may lead to social and political uncertainty

¹⁴ Several studies have tried to establish causality from BC volatility to growth using the instrumental variable regressions. For example, Hnatkovska and Loayza (2005) used the following variables as the instruments of volatility: the standard deviation of the inflation rate, a measure of real exchange rate misalignment, the standard deviation of ToT shocks, and the frequency of systematic banking crises. Martin and Rogers (2000) used the standard deviation of the growth rate of the preceding decade, the initial inflation rate of the decade, the initial level of GDP per capita and the number of revolutions and coups as instruments for developing countries. Mobarak (2005) used diversification as the instrument of volatility. However, exogeneity of these instruments in the long run can be disputed. Bazzi and Clemens (2013) provide an excellent discussion on the problem of instrumental variable estimation in cross-country growth regressions.

that might cause higher volatility next period (at time or interval $\tau+1$).¹⁵ Given that this potential reverse causality is unlikely to be contemporaneous, we rule this out in the panel data that is constructed as average (and standard deviation) over an interval. But the problem persists in the cross-section data because it is constructed by taking average (and standard deviation) for a longer period of time. Since there is no exogenous instrument to correct it, we estimate the cross-sectional specification by OLS that gives the benchmark results and are interpreted as correlation between BC volatility and long-run growth.¹⁶

But construction of BC (and LR) volatility using the filtered data generates another type of reverse causality in the panel data. To see the mechanism, suppose x_t is the growth rate of per capita real GDP at time t . For a specific interval τ , the average growth rate (\bar{x}_τ) is the non-

overlapping average of x_t over 7 periods, i.e. $\bar{x}_\tau = (1/7) \sum_{j=0}^6 x_{t+j}$. On the other hand, BC volatility

is calculated as the standard deviation of the band-pass filtered series of x_t (say, x_t^*) over the

same interval, where $x_t^* = \sum_{q=-3}^{+3} a_q x_{t+q}$ (a_q 's are the filter weights), i.e.,

$sd(x_t^*) = \left[(1/6) \sum_{j=0}^6 (x_{t+j}^* - \bar{x}_\tau^*)^2 \right]^{1/2}$. This shows that average growth rate, the dependent variable in

the regression, is based on x_t data for $(t+j)$ periods, while the BC volatility, the explanatory variable, is based on x_t data for $(t+j+q)$ periods (it also consists data from lagged periods but that does not cause a problem).¹⁷ To address the potential reverse causality generated in the data, we construct a modified filtered series x_t^{**} based on one-sided filter using only lagged value of x_t

¹⁵ The reverse causality can also be positive. Aghion and Banerjee (2005) present a model where the reverse causality is positive but only countries at the intermediate level of financial development are vulnerable to volatility.

¹⁶ The correlation between volatility and growth is arguably no less important. In a different context, Acemoglu, Hassan and Robinson (2011) estimate correlation between the severity of the persecution, displacement, and mass murder of Jews due to the Holocaust and long-run economic and political outcomes in Russia because of the lack of exogenous instruments.

¹⁷ One might argue that both the dependent and independent variable are constructed from the same x_t series but we stress that the empirical growth-volatility relationship is based on this specification.

as $x_t^{**} = \sum_{q=-3}^0 b_q x_{t+q}$, and use the standard deviation of x_t^{**} as the instrument of BC volatility.

Similar identification has also been employed for LR volatility.¹⁸

Measurement errors in BC (and also LR) volatility as a source of endogeneity is less clear although this has been raised by Martin and Rogers (2000). Measurement errors in volatility are less likely to be inherited from measurement errors in GDP. Some countries might purposefully inflate their GDP figures on a regular basis; however, in such a scenario, growth rate calculated from GDP is unlikely to be contaminated by such type of manipulation. One might argue that standard deviation may not represent the true volatility, but this proxy is common in many areas of economics and finance. Nevertheless, we try to address this source of endogeneity, if any, by constructing instrument from within the data, since we believe that exclusion restrictions in cross-country growth regression is almost impossible to satisfy unless someone is lucky enough to find a natural experiment. In order to do it, we order the sample countries by their BC (LR) volatility and construct an ordering score or rank for countries (a value of 1 for the least volatile country and consecutive integers for countries with incremental volatility), which is our instrument for BC (LR) volatility. This identification is based on the assumption that measurement errors do not vary in a way so as to alter the distribution of countries in terms of their BC (LR) volatility. This instrument is by construction highly correlated with BC (LR) volatility but exogenous to the growth rate.

Since we cannot control for omitted variable bias in the Angus Maddison panel data for lack of control variables, we estimate it without any instrumentation (fixed effect regression) and interpret the results as simple correlation.

5. Results

We report $\hat{\gamma}_{1C}$ and $\hat{\gamma}_{1W}$ estimated from cross-section and panel data for different time periods and country groups. The former coefficient represents a credible correlation or an

¹⁸ Similar identification has been employed by Chirinko and Mallick (2014). It is also worth mentioning that construction of BC (and LR) volatility as the standard deviation of x_t^{**} (rather than that of x_t^*) and then using it directly in the regression causes a phase shift. However, this estimation does not qualitatively change our results (not reported).

unbiased causal effect of BC volatility, while the latter coefficient is estimated from the misspecified equation. We also report $\hat{\gamma}_2$, the coefficient on LR volatility, which can also be interpreted as the persistence in volatility, to judge its contribution relative to $\hat{\gamma}_{1C}$ in explaining growth, and also to show the direction of bias in $\hat{\gamma}_{1U}$.

5.1 Correlation between BC volatility and LR growth in the cross-section data

In the following, we report the results from estimation of equations (1a) and (1b) by OLS for different periods (1960-2007,¹⁹ 1960-1980, 1980-2007 and 1970-2007) that are summarized in Table 3. The odd-numbered columns report $\hat{\gamma}_{1C}$ (and also $\hat{\gamma}_2$) estimated from equation (1a). In all periods, $\hat{\gamma}_{1C}$ is insignificant and close to zero (and there is also no consistent pattern in its sign) suggesting a lack of correlation between BC volatility and growth.

The even-numbered columns present $\hat{\gamma}_{1U}$ estimated from the misspecified equation (1b). It is large negative and statistically significant in 1980-2007 and 1970-2007 periods (columns (6) and (8), respectively).²⁰ Given that $\hat{\gamma}_2$ in equation (1a) is negative (and significant) in these two periods, $\hat{\gamma}_{1U}$ is biased downward as shown in equations 5(a)-5(b). Comparing the results from equations (1a) and (1b) for the 1970-2007 period, the coefficient on BC volatility changes from -0.002 to -0.121. The quantitative implication of this difference is huge. One standard deviation increase in BC volatility is associated with only 0.003 percentage point decrease in long-run growth, which is statistically insignificant and also economically trivial. But in the misspecified

¹⁹ The full sample period reduces to 1964-2004 because the first observation is lost after calculating growth rate, and then three observations from each tail are lost because of employing the filter with a 3-year window.

²⁰ As mentioned earlier, private credit data are available for a good number of countries since 1980, and therefore, this variable is controlled only for the 1980-2007 period. The result (not reported) is robust without controlling for it (and also *Polity2*); the coefficient of BC volatility becomes larger in absolute value and significant at a higher level. For example, the coefficient (*t*-statistic) increases (in absolute value) from -0.157 (-1.72) to -0.171 (-2.85). This result suggests the importance of financial development as an important channel through which BC volatility interacts with growth. It is also important to mention that if investment is excluded, the coefficient on BC volatility hardly changes suggesting that investment is not an important channel, which is also consistent with Ramey and Ramey (1995).

equation, the same increase in BC volatility is incorrectly associated with 0.219 percentage point decrease in long-run growth.

Insert Table 3 here

One might suspect that the results from equation (1a) are driven by any multicollinearity between BC and LR volatility. For example, in the 1980-2007 period, $\hat{\gamma}_{LR}$ is -0.157 (significant at 10% level) in the misspecified regression but $\hat{\gamma}_{BC}$ is 0.053 (positive though very close to 0 and insignificant) after including LR volatility in the regression. We rule out such a possibility by calculating the variance inflation factor (VIF) (alternatively, tolerance = 1/VIF). The VIFs (tolerances) of BC and LR volatility are 2.85 (0.351) and 2.80 (0.357), respectively, which are far less (higher) than any conventionally considered critical level. Even if only BC and LR volatility are included in the regression excluding other controls, the VIF (tolerance) is even lower (higher) at 2.31 (0.432).

To further address heterogeneity among countries for reasons other than fluctuations in the trend growth, we perform disaggregated analysis in several ways. First, we divide the sample countries into three groups in terms of their intensity of BC volatility: i) least volatile (0-33 percentile), ii) moderately volatile (33-66 percentile), and iii) most volatile (67-100 percentile). There are 30 countries in each group in the full period, and 36, 32 and 35 countries, respectively, in the 1980-2007 period. We construct dummies for the three volatility categories and interact them with BC volatility. The results are summarized in Table 4. There is no correlation between BC volatility and growth for any of these groups, and the result is robust across time periods and sample countries. However, in the misspecified regression, $\hat{\gamma}_{LR}$ becomes significantly negative for the most volatile group of countries in both 1980-2007 and 1970-2007 periods (columns 6 and 8, respectively).

We now estimate equations (1a)-1(b) separately for different income groups. The results for developing (low and middle income combined) countries, summarized in Table 5, are similar to those for the full set of countries in that there is no correlation between BC volatility and growth. When developing countries are further disaggregated into three groups by their intensity of BC volatility similar to the disaggregation for the full set of countries, the results are also

qualitatively similar (Table 6). There is also no significant correlation for developed (high income) countries, and the sign of $\hat{\gamma}_{1c}$ changes across periods (Table 7).

Insert Tables 4-7 here

The above results indicate an absence of relationship between BC volatility and long-run growth. However, the negative relationship estimated from the misspecified equation (1b) is induced by the missing correlation of LR volatility.

5.2 Correlation using alternative frequency bands and filtering

Previous estimations are based on the implicit assumption that both developed and developing countries are characterized by similar cyclical patterns. Although there is a large literature on business cycles in the context of developed countries, very little is known about business cycles in developing countries. Agénor McDermott and Prasad (2000) point out that there are both similarities (procyclical real wages, countercyclical variation in government expenditures) and differences (countercyclical variation in the velocity of monetary aggregates) between macroeconomic fluctuations in developing and developed countries. Rand and Tarp (2002) demonstrate that developing countries differ considerably in terms of the nature and characteristics of short-run macroeconomic fluctuations. Analyzing a sample of 15 developing countries (five countries each from sub-Saharan Africa, Latin America, and Asia and North Africa), the authors document that average lengths of expansion and contraction are 4.8 and 5.2 years, respectively. This suggests that cycles are generally shorter in developing countries. Male (2009) contrasts this conclusion but stresses that there is heterogeneity at the regional level in that cycles are shorter in Latin America and longer in Asia.

We now calculate BC and LR volatility using an alternative critical periodicity of 5 years for developing countries but retain the same critical periodicity for developed countries. The results, summarized in Appendix A.3, are qualitatively similar to the benchmark results.

We also calculate BC and LR volatility using the Hodrick Prescott (1997) and Christiano and Fitzgerald (2003) band-pass filters. These filters extract the cyclical components, and the trend is retrieved as the residual. Although the H-P filter is optimal for an I(2) process and the C-F filter is optimal for a random walk process, we nonetheless employ them to verify the

robustness of the previous results. We use the same window and periodicity in the C-F filter as in the B-K filter. For the H-P filter, we use a smoothing parameter of 6.25 based on the recommendation by Ravn and Uhlig (2002, p. 371) that the parameter should be adjusted approximately with the fourth power of the frequency change.²¹ The results using both the H-P and C-F filters (Appendices A.4 and A.5, respectively) are very similar to the benchmark results.

5.3 Causal effect of BC volatility in the panel data: the results for IV estimation

We now present the results for contemporaneous effect of BC volatility on growth by estimating equations (2a)-(2b). These equations are estimated by the GMM and the instrumentation has been discussed in Section 4.2. Separate results are estimated for different sample periods and country income groups. All results are summarized in Table 8. Columns (1)-(4) and (5)-(8) present the results for the full period (1960-2007) and the 1978-2007 sub-period, respectively.²² When the endogeneity due to reverse causality generated in BC (and LR) volatility constructed from filtered data are addressed (GMM-1), the results are presented in columns (1)-(2) and (5)-(6). When both sources of endogeneity are addressed (GMM-2), the results are presented in other columns.

Panel-A summarizes the results for all countries. The results are similar under both instrumentations (GMM-1 and -2). There is no effect of BC volatility on growth in equation (2a) after controlling for LR volatility. However, in the misspecified equation (2b), especially under GMM-2, this effect becomes statistically significant at 5% level and also larger in magnitude. The results are robust in both periods. To see the quantitative implication of the misspecification, consider the 1978-2007 period. The estimated coefficient on BC volatility (column (8)) implies that growth rate declines by 0.22 percentage points for one standard deviation increase in BC volatility. However, after correcting the misspecification by including LR volatility in equation (2a), the same increase in BC volatility now leads to only 0.12 percentage point decrease in growth that is also not statistically significant.²³

²¹ STATA also recommends a smoothing parameter of 6.25 for annual data.

²² The effective sample periods 1964-2007 and 1978-2007 cannot be divided into seven equal intervals; therefore, we take average over 9 years for the last interval (1999-2007).

²³ The results follow similar pattern if estimated by OLS without correcting for endogeneity (not reported).

The results for developing (low and middle income) countries, presented in Panel-B, follow similar patterns as in the full set of countries in that there is no effect of BC volatility on growth after correcting for the misspecification. The results for the developed countries, presented in Panel-C are different. There is a significantly positive effect of BC volatility in the 1978-2007 period but the effect disappears when the sample period extends back to 1960. The magnitude of the coefficient on BC volatility does not differ much in the two specifications (equations (2a) and (2b)) which can be understood by a very small (0.09) and statistically insignificant coefficient on LR volatility (column (7)).

It is also imperative to discuss the first-stage results to know the precision of the second-stage results estimated by the GMM. In all cases, the coefficients of the instruments are positive and statistically significant at any conventional level in the regression of both BC and LR volatility on the instruments and other included regressors (not reported). When equation (2b), in which BC volatility is the only endogenous regressor, is estimated by GMM-1 (columns 2 and 6), the F-statistic estimated in the first stage regression is very large suggesting that the results do not suffer from weak instrument problem. In the case of equation (2a) that include both BC and LR volatility and both are treated as endogenous (columns 1 and 5), the values Kleibergen-Paap rk Wald F statistics also corroborate the strength of the instruments. All estimations by GMM-1 are exactly identified. However, in the case of GMM-2 except for the developing countries in the 1978-2007 period and the developed countries in the 1960-2007 period, the over-identifying restrictions are not satisfied as indicated by the p-value of the Hansen J-statistics casting doubt on the validity of these results.

Insert Tables 8-9 here

The results for the effect of lagged volatility on current growth estimated from equations (3a)-(3b) are summarized in Table-9. The results for the full set of countries, summarized in Panel-A, show that there is no effect of lagged volatility. The results hold for both developing and developed countries (Panels B and C, respectively). But, unlike contemporaneous BC volatility, the coefficient on lagged BC volatility is also insignificant in the misspecified regression with the exception that it is positively significant for developed countries in the 1978-2007 period. The first-stage results are similar to the ones in the case of contemporaneous effect.

To summarize, we find that there is no effect of BC volatility on growth in general and for developing countries in particular, while there is a positive effect for developed countries but that is not robust across different time periods. In addition, there is no effect of lagged BC volatility on growth.

5.4 Correlation in the historical (1875-2010) panel data

We now estimate the relationship from the historical data compiled by Angus Maddison for the 1875-2010 period.²⁴ This estimation allows us to verify the results from an alternative dataset and time period. There are 28 countries of which 20 are developed by the current income level (A list of countries is provided in the note below Table 10), and there are 18 observations for each country.²⁵ Due to unavailability of data for control variables, we can control only (log) initial level of GDP, time (interval) dummies, and dummies for major economic episodes: pre-1914, 1914-1945, 1946-1985, and post-1985 periods. As a result, country fixed effects will be correlated with the omitted variables, so we estimate the fixed effect regression. We interpret both the coefficients on BC volatility and its lag as correlation.

Insert Table 10 here

Panels A and B in Table 10 summarize the results for the full set of countries and 20 developed countries, respectively. The results are similar in both panels. There is no contemporaneous correlation between BC volatility and growth. But the correlation becomes negative and significant in the misspecified regression that omits LR volatility. In contrast, there is a significantly positive correlation between lagged BC volatility and growth, but the

²⁴ Data go back to earlier period but the number of countries decreases. For example, data is available since 1820 for only 8 countries (Australia, Italy, Denmark, France, Netherlands, Sweden, UK and USA).

²⁵ In the dataset, consecutive values of real per capita GDP since 1875 are available for 28 countries. The actual time period retained in the analysis is 1879-2007 because the first observation is lost due to calculation of growth rate from level of GDP, and three observations from each tail are lost due to filtering using a 3-year window. The time period is then divided into 18 equal 7-year intervals except the last interval.

correlation would be shown to be stronger both in terms of its magnitude and statistical significance if the misspecified regression were estimated.

Comparison of these results with the previous results from the PWT data shows that the correlation of lagged BC volatility with growth is positive for developed countries although greatly varies across time periods and sample countries, but the relationship is, to a large extent, induced by the missing correlation of (lagged) LR volatility.

5.5 Replication of Ramey and Ramey (1995)

Our final robustness check is to replicate Ramey and Ramey (1995), arguably the most influential study on the volatility-growth relationship, using their data. We replicate their basic cross-sectional specification because it is comparable to our specification. Using the PWT 5.6 data, Ramey and Ramey estimated the relationship for two sets of countries: i) a full sample of 92 countries for the 1960-1985 period, and ii) 24 OECD countries for the 1950-1988 period. It is worth mentioning that the PWT data has been revised several times and subsequent revisions are not strictly comparable.²⁶

Ramey and Ramey calculated growth rate and volatility from the “Real GDP per capita, 1985 international prices: Chain Index (RGDPCH)” (their Data Appendix, p. 1150). This is not the appropriate variable to compare the growth rates over time and across countries; the appropriate series would be the growth of GDP at constant national prices (see, Feenstra, Inklaar and Timmer (2013; PWT 8.0 User Guide, p. 25). GDP at constant national prices data were not available in the PWT 5.6, so Ramey and Ramey conducted the best possible exercise given the data at hand. Another useful and informative exercise would be to replicate Ramey and Ramey using the appropriate GDP measure from the PWT 8.0 for the same set of countries and time

²⁶ Ponomareva and Katayama (2010) replicated Ramey and Ramey and found that conclusions based on one version of the PWT may not hold under another version; however, growth and uncertainty are negatively and significantly related for countries with the worst data quality. Dawson et al. (2001) also replicated Ramey and Ramey and found that the results do not hold after controlling for data quality.

period as in the PWT 5.6. However, we are able to do it only for their 24 OECD countries as data is not available for a good number of countries in their full sample.²⁷

Insert Table 11 here

The results are summarized in Table 11. Panel A reports the results for 92 countries for the 1960-1985 period. In column (1), the coefficient on volatility (standard deviation of the growth rate) in the specification without any control reported by Ramey and Ramey is reproduced—it is -0.15 with a *t*-statistic of -2.3 (which increases to -2.6 after correcting heteroskedasticity). However, as we discuss in detail in Section 6, the standard deviation of the raw or unfiltered growth rate differ from our measure of BC volatility. When BC volatility calculated as the standard deviation of the band-pass filtered series and used instead in the same regression, its coefficient remains very close at -0.16 with a *t*-statistic of -2.59 (column (2)). When their controls— initial income, average population growth, average investment share of GDP and initial human capital—are included in the regression, the coefficient on BC volatility decreases to -0.109 with a *t*-statistic of -1.636 (which slightly falls short of 10% level of significance) (column (3)). But after controlling for LR volatility, the coefficient on BC volatility decreases to almost zero (0.006) with a very low *t*-statistic of 0.066 (column (4)).

The results for the 24 OECD countries are summarized in Panel B. The coefficient on BC volatility in the specification with all controls is large negative (-0.408) and significant (*t*-value of -2.46), and does not meaningfully change after controlling for LR volatility (columns (3) and (4)). However, when we replicate these results (with same countries, time period and controls) using the growth of GDP at constant national prices data from the PWT 8.0 (Panel C), the coefficient on BC volatility is small and statistically insignificant both without and with controlling for LR volatility, and the sign differs in the two specifications. These results are in

²⁷ In the PWT 8.0, data are not available for the following 9 countries in the Ramey and Ramey sample: Afghanistan, Algeria, Guyana, Haiti, Myanmar (Burma), Nicaragua, Papua New Guinea, Yugoslavia (country disintegrated), and Zaire. For Iraq, Sudan and Swaziland, GDP data start from 1970 and for Liberia from 1964. Therefore, a total of 13 countries are missing from the sample.

line with our previous results, and suggest a lack of relationship between BC volatility and growth.

6. Volatility vs. its persistence

LR volatility can also be interpreted as persistence in volatility (Levy and Dezhbakhsh, 2003; Ascari and Sbordone, 2014). In the following, we compare the relative importance of BC volatility and persistence in volatility in explaining long-run growth.

We have found that there is no effect of either contemporaneous BC volatility or its lag on growth, but there is negative contemporaneous effect in the misspecified regression. Moreover, the results also show a negative and significant effect of LR volatility on growth in general and for developing countries in particular in both panel and cross-section data (correlation in the latter case) (Tables 3-6, and Panels A and B in Table 8). The relationship of LR volatility for developed countries lacks any definite pattern; for example, in the cross-section data there is a positive correlation of LR volatility in the post-1970 period (column (5) and (7) in Table 7), but a negative effect in the panel data in the full sample period (column (3) in Table 8, Panel C). These findings signify the importance of LR volatility in explaining growth. They also imply that if LR volatility is omitted from the regression, its effect will be, to a large extent, reflected in the coefficient on BC volatility.

Several studies (including Ramey and Ramey, 1995) use standard deviation of (unfiltered or raw) growth rate as a proxy for BC volatility. This measure is based on the assumption of a constant trend, while BC volatility calculated as the standard deviation of the cyclical components assumes a time varying trend. As shown in the introduction, total variance of growth rate is sum of the variances of its cyclical and long-run components. Therefore, volatility measured as the standard deviation will capture the combined effects of both BC and LR volatility. In other words, the effect of missing LR volatility will be reflected in the coefficient on BC volatility in the misspecified regression or in the coefficient on total volatility (the standard deviation of the unfiltered or raw series).

Insert Table 12 here

To verify the above argument, we calculate the standard deviation of (unfiltered or raw) growth rate and for convenience define it as total volatility. We now estimate the coefficient on total volatility to compare it with $\hat{\gamma}_2$ (coefficient on LR volatility) and $\hat{\gamma}_{1U}$ (coefficient on BC volatility in the misspecified equation) estimated earlier. Some selected results based on the significance of $\hat{\gamma}_2$ and/or $\hat{\gamma}_{1U}$ are presented in Table 12. Consider the cross-sectional results for the 1980-2007 period presented in columns (1)-(3) in Panel A. The coefficient on total volatility is reported in column (1). It is negative at -0.187 and statistically significant at any conventional level; quantifying this result, one standard deviation increase in total volatility is associated with 0.35 percentage point decrease in growth. Columns (2) and (3) reproduce the results for BC and LR volatility estimated from the same specification and reported earlier in columns (5) and (6) in Table 3, respectively. Note that there was no correlation of BC volatility ($\hat{\gamma}_{1C}$ became insignificant) after correcting the misspecification but a significantly negative correlation of LR volatility emerged (a value of $\hat{\gamma}_2$ at -0.458 and statistically significant at any conventional level). The latter result can be quantified as 0.48 percentage point decrease in growth associated with one standard deviation increase in LR volatility. But in the misspecified regression that omitted LR volatility, $\hat{\gamma}_{1U}$ was estimated at -0.157 and was significant—it would incorrectly lead to the inference that one standard deviation increase in BC volatility would be associated with 0.26 percentage point decrease in growth. These results support our argument that the contribution of LR volatility is misconstrued as the contribution of total volatility or that of BC volatility because of misspecification. Similar results from panel data are presented in Panel B.

To summarize this section, it is not BC volatility but persistence in volatility that affects (is associated with) growth, and the effect (association) may differ across time periods and country groups.

7. Contribution to the literature

Our paper is situated in a large body of literature on the volatility-growth relationship but can be distinguished by its contribution in addressing the persistence in growth volatility. The issue of persistent fluctuations has been raised in the cross-country macroeconomic literature in several contexts. In the following, we discuss our contributions in this literature.

Fatás (2000a, 2000b) document a strong positive correlation between long-run growth rates and persistence of output (not growth) fluctuations in a cross section of countries. The results suggest that volatility of the permanent component of output is larger for countries with high growth rates. In contrast, we deal with a different question regarding growth volatility, and document that the relationship between growth and persistence in growth volatility, although generally negative, differ across time periods and country groups.

Some studies have distinguished volatility between its unexpected (uncertain) and expected components. It is imperative to distinguish between uncertainty in, and volatility of, growth. Uncertainty accounts for only the unpredicted component of growth, while volatility accounts for both predicted and unpredicted components (Wolf, 2005).²⁸ Uncertainty is usually calculated as the residual of a forecasting equation where GDP growth is regressed on its own lags and linear (and quadratic) trends (see, Ramey and Ramey, 1995; Fatás, 2002; Rafferty, 2005). Although introducing the trends removes low frequency movements from the data and therefore is comparable to the band-pass filtered growth, BC volatility in our paper is a measure of *ex post* realized volatility as opposed to uncertainty. Ramey and Ramey (1995) and Rafferty (2005) included in the regression both unexpected and expected volatility, where the latter was calculated as the standard deviation of the fitted value of growth rate. Our measure of LR volatility is different from the expected volatility in the same way as low-pass filtering differs from fitting. The aim of low-pass filtering is to retain slow-moving values, whereas fitting concentrates on achieving as close a match of data values as possible. Furthermore, filtering, unlike fitting, does not involve use of an explicit function form. These differences are also manifest in the differences in the results discussed below.

Ramey and Ramey (1995) found that both the coefficients on unexpected and expected volatility were insignificant (negative and a low *t*-statistic) in a sample of 92 countries. On the other hand, in a sub-sample of OECD countries, the coefficient on unexpected volatility was negative and highly significant, and the coefficient on expected volatility was positive and significant.²⁹ On the other hand, we do not find any effect of BC volatility but a negative and

²⁸ Bloom (2014) discusses different measures of uncertainty employed in the literature.

²⁹ Kormendi and Meguire (1984) earlier found that standard deviation of monetary shocks has a significant negative effect and standard deviation of growth rate has a significant positive effect on growth. Ramey and Ramey conjectured that the standard deviation of monetary shocks may be correlated with unexpected volatility. Thus, the

significant effect of LR volatility on growth, especially for developing countries. Similarly, using the Angus Maddison historical data for 18 developed countries for the 1880-1990 period, Rafferty (2005) found that unexpected volatility reduces, and expected volatility increases, long-run growth. Using the same data, we instead find no association of BC or LR volatility with growth.

Hnatkovska and Loayza (2005) distinguish between “regular” and “crisis” volatility and show that only “crisis” volatility is statistically significant for explaining growth when both types of volatility are included in the regression. The authors define “crisis” volatility as the portion of the standard deviation of GDP growth that corresponds to downward deviations below a certain threshold. They set the threshold equal to one standard deviation of the world distribution of overall volatility measures. Regular volatility, on the other hand, is defined as the portion of the standard deviation of GDP growth corresponding to deviations that fall within the threshold. Their distinction of the two types of volatility can be compared to our disaggregation of countries in terms of their intensity of BC volatility (Tables 4 and 6). But our contribution lies in accounting for LR volatility for which Hnatkovska and Loayza have no counterpart.

Aguiar and Gopinath (2007) point out that shocks to trend growth can be the primary source of fluctuations in the emerging market economies as opposed to transitory fluctuations around the trend. The authors document that these economies on average have a business cycle twice as volatile as that of their developed counterparts. They measure business cycle by volatility of the H-P band-passed filtered log output, and volatility of the first difference of unfiltered log output (this corresponds to our measure total volatility in Section 6). They also document that the first-order autocorrelation of unfiltered output growth is twice as large, suggesting greater persistence in business cycles in emerging economies (their Table 1, p. 74). Although our study differs from theirs in regard to the research question and also in terms of the definition and calculation of volatility, we document in Table 2 that both BC and LR volatility decrease with income level, but so does their ratio. This implies that LR volatility relative to BC volatility is also larger in developed than in developing countries.

positive effect of the standard deviation of output in Kormendi and Meguire may be capturing the effect of predictable movements in growth, similar to their expected volatility.

Our paper is also situated in a burgeoning literature on growth spells first pioneered by Pritchett (2000).³⁰ Pritchett pointed out heterogeneity among countries in terms of instability in growth rates over time. Country experiences differ enormously by steady growth, rapid growth followed by stagnation, rapid growth followed by decline or even catastrophic falls, continuous stagnation, or steady decline. He cautioned that econometric growth literature using the panel nature of data may be uninformative to account for the heterogeneity. Our motivation and approach to account for heterogeneity address this concern.

8. Concluding remarks

This paper finds that at the cross-country level there is no relationship between BC volatility and long-run growth. The main departure from the extant empirical literature is in accounting for fluctuations in the trend growth that we refer to as LR volatility. However, a significant negative relationship can be found, especially for developing countries, in the misspecified equation that omits LR volatility, which is consistent with the findings in the literature. Our measure of LR volatility—standard deviation of the low-pass filtered growth rate—also represents persistence in volatility. We find that persistence in volatility negatively impacts on growth, especially for developing countries. We also test the theoretical prediction of the effect of BC volatility in previous period on current growth but do not find any effect. There might be an asymmetry in the effect of BC volatility in that volatility in expansionary and contractionary phases may have differential impacts on growth, which can be an interesting topic to explore further.

Our results have important implications in light of the recent global financial crises. The large decline in output and very slow recovery after the 2008 recession compared to the previous recessions suggest a reduction in the trend growth rate in many developed countries. But such contractions are more frequent in developing than developed countries, but the causes and remedies of such fluctuations are largely unknown and thus require further investigation. Our finding of lack of correlation between BC volatility and growth does not necessarily imply irrelevance of stabilizing business cycles since cyclical fluctuations may affect heterogeneous

³⁰ Some recent papers have attempted to explore the determinants of the growth spells (for example, Berg, Ostry and Zettelmeyer, 2012; Bluhm, Crombrughe and Szirmai, 2014).

agents differently that is not evident at the aggregate data.³¹ Our results have also important implications for cross-country growth regressions in that ignoring heterogeneity among countries may lead to wrong conclusions.

³¹ Lucas (1987) documented that the welfare effects of eliminating business cycle are very small, well below 1% of national income. Krusell and Smith (1999) investigate these effects in a model with substantial consumer heterogeneity that arises from uninsurable and idiosyncratic uncertainty in preferences and employment status. The results suggested a welfare loss larger than Lucas (1987), but still very small. However, this model is based on the assumption that individual shocks are unaffected by the removal of the cycles. If this assumption is relaxed, the average gain from eliminating cycles is as much as 1% in consumption equivalents, which is large for both the poor and rich (Krusell et al., 2009).

Figures in parentheses are standard deviations. Figures in brackets are 95% confidence interval.

Note: The ratio of BC volatility to LR volatility has been calculated for each country, and the average of this ratio is reported in column (4).

Table-3: Cross-sectional estimation by OLS (all countries)

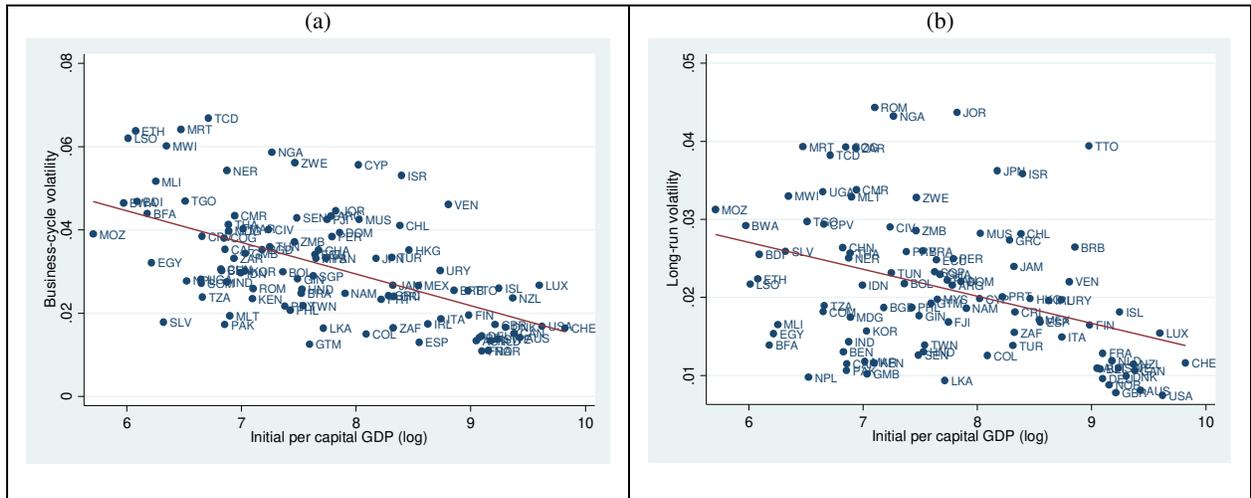

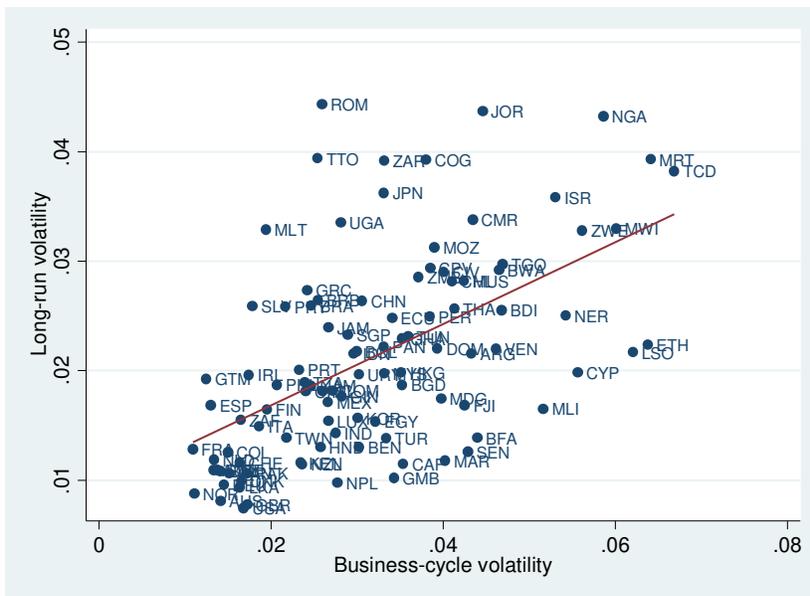

Figure 3: Relationship between BC and LR volatility

Appendix

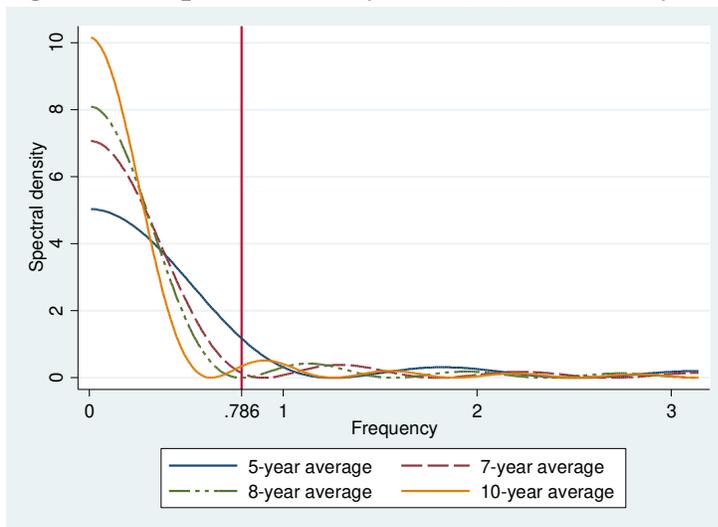

A.1: Comparison of spectral densities

The spectral density for averaging over T years is given by:

$(1/T)^2 (1 - \cos T\omega) / (1 - \cos \omega)$, where ω is the frequency ranging between 0 and π (for

derivation, see Sargent, 1987, p. 275). The spectral densities for $T = 5, 7, 8$ and 10 are displayed in Appendix Figure A.1. They are normalized using appropriate scalars so that the area under the curves are equal. A vertical line is drawn at 0.786 to mark the critical frequency that separates the long-run from cyclical components. Note that the periodicity (p) and frequency are inversely related by the formula: $p = 2\pi / \omega$. For a critical periodicity of 8 years, the corresponding critical frequency is 0.786 . It can be seen from the graph that 5-year averaging does not reweight the variances of the raw series enough across low frequencies, thus the transformed data are more likely to be contaminated by high frequencies. The area under the spectral density to the right of the vertical line is 14% of the total area for 5-year averaging. The area substantially reduces 9.3% for 7-year averaging; it remains the same for 8-year averaging and reduces only to 8.8% for 10-year averaging.

Figure A.1: Spectral density for 5-, 7-, 8- and 10-year averaging.
