Tourism and economic growth revisited: Empirical evidence from a Panel VAR approach

Nikolaos Antonakakis*[†] Mina Dragouni [‡] Bruno Eeckels[§] George Filis[¶]

October 23, 2015

Abstract

The current literature on the tourism-economic growth causal relationship has not yet reached to a clear empirical consensus. The aim of this paper is to revisit this ambiguous relationship by examining the dynamics between tourism and economic growth from a more holistic view. In particular, we focus on 113 countries over the period 1995–2011, which we group into clusters based on six different criteria. A Panel Vector Autoregressive model is employed to reveal the tourism–economy interdependencies across these clusters. Overall, our findings cannot support the tourism–led economic growth hypothesis in any of our clusters. Rather, the economic–driven tourism growth hypothesis seems to prevail in most cases, although some short-lived bidirectional causalities are also identified. Thus, depending on the level of tourism competitiveness and economic development different policy implications apply.

Keywords: tourism income, economic growth, panel vector autoregressive model, generalised impulse responses, clusters

1 Introduction

The link between tourism and economic growth has received considerable attention and generated a great amount of research in international tourism studies. Relevant scholarly work on this topic sought to address the question of whether there is a causal direction of effects between the tourism sector and national economies. This question was mainly approached through time-series analyses of individual countries, or on some occasions, through cross-section and panel data models (see, *inter alia*, Chen and Chiou-Wei, 2009; Apergis and Payne, 2012; Chang et al., 2012; Chatziantoniou et al., 2013).

The bulk of these studies postulate the existence of spillover effects between the two factors, which run either from tourism to the economy (the tourism-led economic growth hypothesis) or from the economy to tourism (the economic-driven tourism growth hypothesis) (see, Parrilla et al., 2007; Payne and Mervar, 2010; Schubert et al., 2011, among others). At the same time, there are researchers who support the existence of bidirectional causalities or no causalities at all (see, for example, Katircioglu, 2009; Ridderstaat et al., 2014; Antonakakis et al., 2015). The aim of this paper is to shed some more light on this ambiguous relationship by examining the dynamic links between tourism and economic growth in 113 countries over the period 1995-2011.

In particular, we attempt to disentangle the intricate tourism and economic growth relationship through the application of a Panel Vector Autoregressive model (PVAR) approach along with impulse response functions to data on tourism (proxied by either international tourism receipts, international tourism expenditures or international tourist arrivals) and economic growth. We argue that the degree of economic growth that is attributable to tourism (or the reverse) may depend on various country-specific characteristics. For this reason, we cluster our sample countries on the basis of six different criteria: their (a) cost of living, (b) level of development, (c) government effectiveness, (d) political regime, (e) level of tourism specialisation and (f) tourism competitiveness.

This is an effort to build a comprehensive and up-to-date study on the tourism-economic growth nexus across the globe that takes into account the key dynamics that influence tourism and broader economic performance.

The advantages of using a panel VAR methodology relative to methods previously used to examine the relation between tourism and economic growth are several. First, VARs are extremely useful when there is little or ambiguous theoretical information regarding the relationships among the variables to guide the specification of the model. Second, and more

importantly, VARs are explicitly designed to address the endogeneity problem, which is one of the most serious challenges of the empirical research on tourism and economic growth. Researchers such as Lee and Chang (2008), Holzner (2011) and Chang et al. (2012) raise the issue of endogeneity. VARs help to alleviate the endogeneity problem by treating all variables as potentially endogenous and explicitly modelling the feedback effects across the variables.

Third, impulse response functions based on VARs can account for any delayed effects on and of the variables under consideration and thus, determine whether the effects between tourism and growth are either short-run, long-run or both. Such dynamic effects cannot be captured by panel regressions. Forth, panel VARs allow us to include country fixed effects that capture time-invariant components that may affect tourism and growth, such as country size. Fifth, time fixed effects can also be added to account for any global (macroeconomic) shocks that may affect all countries in the same way. Last but not least, panel VARs can be effectively employed with relative short-time series due to the efficiency gained from the cross-sectional dimension.

The results of this study find no support for the tourism-led economic growth hypothesis in either developed or developing economies. Rather, developing economies present an economy-driven relationship with their tourism sector, whereas developed ones exhibit no causalities, especially in the long-run. This finding suggests that tourism does not yet serve as a strong driver for economic development or the elimination of poverty, which may be due to the high tourism spending that leaks away from poor destinations. In addition, countries with highly competitive tourism product – in terms of price, government effectiveness, political stability and high number of world heritage sites – do not exhibit any relationship between tourism and the economy, and only when competitiveness levels are moderate a mutual causal relationship is observed.

In short, these results are important for policy makers for countries that belong to specific clusters. For instance, the neutral relationship between tourism and economic growth that holds for the more mature and highly specialised groups of countries, suggests that their policymaking for tourism should be independent from their other economic activities. On the other hand, in developing and less tourism-competitive contexts, future policies need to consider the restructuring of the tourism sector in order to decrease tourism income leakages and increase tourism impact on general growth. At the same time, poverty-alleviation strategies should perhaps consider placing more emphasis on other sectors of the economy, rather than tourism, as drivers for development.

The rest of this paper is structured as follows. Section 2 presents a review of the relevant

literature. Section 3 describes the data and classifications used for this study, whereas section 4 presents the econometric approach. Section 5 reports the empirical results from our analysis and section 6 concludes the paper.

2 Literature review

During the past decades, tourism studies exhibited a growing interest in the relationship between tourism and the wider economy. Relevant work sought to explore the causal direction of effects between a country's international tourism presence and its overall economic performance. In particular, they attempted to define whether tourism activity drives the growth of host economies or whether national economies prompt tourism expansion. The product of this extended line of enquiry is a mosaic of different, often opposing interpretations that render this area of research inconclusive and still open to discussion.

More specifically, there is a considerable number of studies which provide evidence of the existence of a unidirectional relationship, either from tourism to the economy – also known as the tourism-led economic growth (TLEG) hypothesis – or from the economy to tourism – the so-called economic-driven tourism growth (EDTG) hypothesis. Indicatively, the empirical work of Parrilla et al. (2007) in Spain, Schubert et al. (2011) in Antigua and Barbuda and Eeckels et al. (2012) in Greece advocate for the TLEG hypothesis, suggesting that the tourism specialisation of these countries enhances their overall growth rates. On the other hand, Payne and Mervar (2010) in Croatia, Tang (2011) in Malaysia and Chatziantoniou et al. (2013) in France hold that it is the economic growth of state economies that stimulates tourism development and not its antipode.

Apart from the unidirectional hypotheses, some scholars have found that the causal relationship between tourism and the economy can be of bilateral character running in both directions. For instance, the findings of Chen and Chiou-Wei (2009) in South Korea and Ridderstaat et al. (2014) in Aruba lend support to the bidirectional hypothesis, according to which there are mutual influences across the tourism-economy nexus. At the same time, there are occasions in which all the aforementioned propositions are rejected, as in the cases of Katircioglu (2009) in Turkey and Tang and Jang (2009) in the US where no causal links between the two factors can be confirmed. Furthermore, Antonakakis et al. (2015) find that the tourism-economic growth relationship is not stable over time; rather, it is very responsive to major economic events.

It is apparent that the existing literary work does not provide a single interpretation, which

can describe the tourism–economy dipole catholically. It is also worth commenting that in their majority, relevant studies narrow their focus on specific case–study areas. However, researchers such as Lee and Chang (2008) and Dritsakis (2012) argue that a cross–sectional analysis of the tourism–economy dynamics allows for a more in–depth and comparative examination of different groups of countries. In addition, it is plausible to propose that the use of panel data can decrease endogeneity through the consideration of specific country effects, omitted variables, reverse causality and measurement error.

Indeed, there is an emerging strand of the literature which follows the panel data approach. Studies across this path of research most commonly group their countries according to their geographical proximity. For example, Narayan et al. (2010) explore four Pacific islands, whereas Dritsakis (2012) examines a selection of Mediterranean destinations. Using panel cointegration tests, both studies postulate the TLEG hypothesis. Further, Apergis and Payne (2012) choose to investigate nine Caribbean states where the panel error correction model reveals bi–causal links. Similarly, Lee and Brahmašreṇe (2013) employ both techniques for 27 European Union member countries confirming a positive effect of tourism on economic growth.

There are also some studies that use panel data comprising countries from all across the globe. Indicatively, Holzner (2011) examines 134 countries and observes that tourism impacts positively on national economies although not at a particularly high degree. Further, Ivanov and Webster (2013) consider the effect of globalisation on tourism’s contribution to economic growth in 167 countries, concluding that globalisation plays no significant role.

The focus on a large number of countries has certain advantages, nevertheless sensitivity analysis, through the classification of countries into different groups, could provide a more in–depth insight on the tourism–growth relationship. In this respect, there are some papers that classify their sample countries based on specific criteria.

A characteristic example is the work of Lee and Chang (2008) who apart from a geographical classification (Asian, Latin American and Sub-Saharan African), they also divide their 55 sample countries into OECD and non–OECD members. The researchers report that the nature of the tourism–economic growth relationship demonstrates differences depending on their region or OECD membership. For example, there is a long–run TLEG causality for OECD countries, while for non–OECD countries this causality is bidirectional. The latter finding is also reported for Latin America and sub–Sahara Africa but no long–run relationship is confirmed for Asia.

Another case in point is that of Sequeira and M. Nunes (2008) who divide their case–study areas in small (based on demographics) and poor countries (based on per capital GDP) to

investigate whether the effect of tourism on the economy is significantly higher for these clusters as compared to international average. They demonstrate that tourism specialisation is more crucial for poor countries; a case that does not hold for small ones. Similar studies that group countries based on the type of their economy are these of Seetanah (2011), who concentrates on a sample of island economies and reports bidirectional causality between tourism and economic growth, and Chou (2013), who narrows his enquiry down to transition economies using panel Granger causality tests, yet no clear pattern is revealed.

Apart from the aforementioned, researchers may employ alternative classifications to filter their enquiry of the tourism–economy relationship. For instance, Arezki et al. (2009) assess 127 countries, using as an indicator their tourism specialisation based on their number of UNESCO World Heritage Sites (WHS). They report that the latter increases the positive effects of tourism on economic growth. More interestingly, Chang et al. (2012) group 159 countries into two clusters (high and low regimes) for each of three classifications; their trade openness, their investment share to GDP and their share of government consumption to GDP. They find evidence that countries which belong to low regimes tend to exhibit a stronger TLEG relationship whereas economies at high regimes do not always enjoy significant tourism effects.

As encapsulated in the previous paragraphs, scholars have recently shown a strong interest in examining multiple countries rather than isolated cases. However, the vast majority of these studies either use no or a mere classification for sample countries, such as a geographic–based characteristic or an economic criterion. There are only but few attempts to introduce various classifications within the same study (as in the case of Chang et al., 2012). Furthermore, all papers that use panel data and/or country classifications select *a priori* a causal relationship, which could flow from either tourism or the economy. This paper aims to extend this strand of the literature, by analysing panel data through a complete set of six characteristics, as it will be explained in section 3, using a PVAR approach, which allows the data itself to reveal the actual causal direction, instead of *a priori* defining the nature of this relationship.

3 Data

In this study we collect annual data from the World Development Indicators database maintained by the World Bank for per capita international tourism receipts (ITRCPT), tourism expenditures (ITEXP) and tourist arrivals (ITARR) as a percentage of GDP, over the period 1995–2011 for 113 developed and developing countries (totalling 1921 observations). The use of three different

proxies for tourism income was chosen for robustness purposes. However, for the sake of brevity, we present the findings that are based only on international tourism receipts. The results from using tourism expenditures and tourist arrivals are qualitatively similar and available from the authors upon request.

Furthermore, we obtain annual data for real GDP per capita (in 2005 US\$, GDPPC), level of development, government effectiveness (GOVEFF), polity IV index (POLREG), number of UNESCO WHS (TOURSPEX) and travel and tourism competitiveness index (TTCI), as criteria for our classifications of countries. Real GDP per capita and government effectiveness scores were obtained from the World Development Indicators database maintained by the World Bank. The classification of the countries between developed and developing follows the United Nations' classification. Data for the polity IV index are accessed through the Polity IV project website (www.systemicpeace.org/polity/polity4.htm). Finally, information on the number of UNESCO WHS is retrieved from UNESCO's website (whc.unesco.org/en/list), whereas data regarding the travel and tourism competitiveness index are acquired from the World Economic Forum (www.weforum.org/reports/travel-and-tourism-competitiveness-report-2013).

Based on the aforementioned data, we proceed with the classification of the 113 countries using the following criteria:

a. *Cost of living.* We classify countries into three distinct groups based on their GDP per capita. The rationale behind this is that high costs of living would imply high relative prices within the destination and the reverse. Thus, tourism prices, shaped largely by the cost of living in one destination and compared to tourism prices/cost of living in alternative destinations can influence affordability and destination choice (Song and Wong, 2003). On this premise, it will be interesting to investigate whether they also influence tourism success in stimulating the economy. Figure 1 demonstrates countries classification from the least expensive to the most expensive, moving from cluster 1 to 3. We have also considered the income group classification of the World Bank and the results are qualitatively similar. However, for brevity we do not report these results here but they are available upon request.

[Insert Figure 1 around here]

b. *Level of development.* We distinguish between developed and developing countries to assess whether any differences exist between the way that tourism affects their economies. This is a particularly current issue given that tourism is often presented as a driver for poverty alleviation (see, for instance, UNWTO and SNV, 2010). For this to hold, we would expect a TLEG

relationship in developing economies. In fact, the study of the tourism–economy relationship in the context of developing countries has attracted some attention and was not always backed up by empirical evidence (see, inter alia Ekanayake and Long, 2012). Thus, it is considered valuable to also use this clustering and try to shed some more light on this critical question. Table 1 provides a list of developed and developing countries.

[Insert Table 1 around here]

c. *Government effectiveness.* We consider some additional parameters, such as a country’s level of bureaucracy, given that this can also influence the success of its tourism product. One salient example is the ease of issuing a visa, which is proven to encourage visitation decisions (Cheng, 2012). Further, government–led administrative tasks which support tourism operations – such as infrastructure provision – can influence the impact that the sector has on the national economy. Similarly, taxes levied on tourists and tourism–related businesses need to be redistributed efficiently in order to make a positive impact (Gooroochurn and Sinclair, 2005). Overall, governments play a central role in tourism as they provide the regulations for tourism planning and management and thus, it is plausible to take their effectiveness into account. Figure 2 illustrates the classification of our sample countries according to this criterion. The level of effectiveness increases as we move from cluster 1 to 3.

[Insert Figure 2 around here]

d. *Political regime.* We distinguish countries based on their level of democracy. According to the literature, we argue that more democratic countries exhibit higher political stability, which in turn encourages economic development and tourism activity. Interestingly, there is evidence that extended political unrest, as compared to one-off short-term political incidents, has remarkably more devastating results for tourism (Fletcher and Morakabati, 2008). Thus, it makes sense to assume that long-term political turbulence can severely hit tourism and the economy as a whole. Figure 3 presents this grouping of countries, based on the polity IV index, where cluster 1 denotes authoritarian or hybrid regimes (i.e. a mix of democratic regimes with autocratic traits), 2 refers to democracy and 3 to full democracy.

[Insert Figure 3 around here]

e. *Level of tourism specialisation.* We group countries based on their number of UNESCO WHS, with the more WHS to reflect more specialised destinations, similarly to Arezki et al. (2009). The

WHS list may include monuments, groups of buildings, forests, lakes, mountains and other areas of special cultural and/or physical significance (UNESCO, 1972). It is a list with international geographic coverage, recognised by 191 countries. As argued by Arezki et al. (2009) and Yang et al. (2010), the existence of a high number of sites ascribed with the UNESCO status is likely to affect growth through tourism activity. Indeed, the WHS list has been evolved into a strong marketing tool for tourism, although some researchers have recently raised their doubts with regards to the WHS fostering effect on tourism and economic growth (see, for instance, Cellini, 2011; Huang et al., 2012). Figure 4 demonstrates this classification, with cluster 1 being the countries with the lowest and 3 the countries with the highest levels of tourism specialisation.

[Insert Figure 4 around here]

f. *Tourism competitiveness.* We adopt the travel and tourism competitiveness index that combines some of the aforementioned characteristics. More specifically, TTCI is constructed on the basis of policy rules and regulations, which relate to our government effectiveness and political regime criteria here, price competitiveness which is approximated by the cost of living in our study, and cultural resources, which are represented by the tourism specialisation number of WHS factor we employ. Thus, the tourism competitiveness clustering will also allow us to compare and corroborate our TTCI results with the results of individual criteria. Table 2 provides the list of countries based on this categorisation, with cluster 1 being the countries with the lowest and 3 the countries with the highest levels of tourism competitiveness.

[Insert Table 2 around here]

Descriptive statistics of each variable and across country groups are presented in Tables 3 and 4.

3.1 Panel unit root tests

The first step for the investigation of causality is to determine whether the series has any integration orders. For this purpose, this study employs panel unit root tests developed by Levin et al. (2002) (hereafter LLC) and Im et al. (2003) (hereafter IPS).

The LLC (2002) unit root test considers the following panel ADF specification:

$$\Delta \ln Y_{it} = \rho_i Y_{it-1} + \sum_{j=1}^{p_i} \delta_{i,j} \Delta \ln Y_{it-j} + \varepsilon_{it}, \quad (1)$$

where Y_{it} is a vector of our key endogenous variables: tourism income per capita growth and real GDP per capita growth.

The LLC (2002) assumes that the persistence parameters ρ_i are identical across cross-sections (i.e., $\rho_i = \rho$ for all i), whereas the lag order p_i may freely vary. This procedure tests the null hypothesis $\rho_i = 0$ for all i against the alternative hypothesis $\rho_i < 0$ for all i . Rejection of the null hypothesis indicates a possible panel integration process.

The IPS (2003) test, which is also based on Eq. (1), differs from the LLC test by assuming ρ_i to be heterogeneous across cross-sections. The IPS tests the null hypothesis $H_0: \rho_i < 0$ against the alternative hypothesis $H_1: \rho_i < 0, (i = 1, \dots, N_1); \rho_i = 0, (i = N_1, \dots, N)$ for all i . Acceptance of the alternative hypothesis allows the individual series to be integrated.

The LLC and IPS tests were executed on data both in levels and first differences of the natural logarithms, and results were reported in Table 5. It is evident that all variables are stationary in first differences, while the level results indicate the presence of a unit root in general.

[Insert Table 5 here]

3.2 Panel Granger-causality

Next we examine the direction of causality among GDP per capita growth and tourism income per capita growth in a panel context. The Granger causality test is as follows:

$$\begin{aligned}\Delta \ln g_{it} &= \alpha_{1t} + \sum_{l=1}^{mlg_i} \beta_{1i,l} \Delta \ln g_{it-l} + \sum_{l=1}^{mli_i} \gamma_{1i,l} \Delta \ln ti_{it-l} + \varepsilon_{1it} \\ \Delta \ln ti_{it} &= \alpha_{2t} + \sum_{l=1}^{mlg_i} \beta_{2i,l} \Delta \ln g_{it-l} + \sum_{l=1}^{mli_i} \gamma_{2i,l} \Delta \ln ti_{it-l} + \varepsilon_{2it},\end{aligned}\quad (2)$$

where index i refers to the country, t to the time period ($t = 1, \dots, T$) and l to the lag. $\Delta \ln g$ denotes the real GDP per capita growth, $\Delta \ln ti$ denotes tourism income per capita growth (as this is approximated by tourism receipts, tourism expenditures and tourist arrivals), and ε_{1it} , ε_{2it} and ε_{3it} are supposed to be white-noise errors.

For instance, according to model (2), in country group i there is Granger causality running only from ti to g if in the first equation not all γ_{1i} 's are zero but all β_{1i} 's and δ_{1i} are zero. The Chi^2 statistic tests the null of no causal relationship for any of the cross-section units, against

the alternative hypothesis that causal relationships occur for at least one subgroup of the panel. Rejection of the null hypothesis indicates, for example, that ti Granger causes g for all i .

The results of the panel Granger-causality test are reported in Table 6.

[Insert Table 6 here]

According to these results, some interesting patterns are revealed. In particular, it is evident that economic growth primarily drives tourism growth and this is a first indication that possibly it is the EDTG that prevails. Nevertheless, there are cases (such as in the GOVEFF3 and TOURSPEC3 clusters), where a bidirectional causality is demonstrated, suggesting that in countries with greater government effectiveness and tourism specialisation there is a feedback effect between the two variables. In addition, a TLEG relationship is reported in the case of COSTLIV3 cluster. Overall, the inference that we draw from this preliminary analysis is that the choice of different criteria and clusters adds value to the discussion of the tourism–growth relationship, given that heterogeneous behaviour is observed. Although the economic growth is the prevailing driver, there is evidence of heterogeneity among the Granger causality test in many of the country groups, which motivates the use of generalised forecast error variance decomposition in our impulse response analysis (for more details, please refer to the next section).

4 Empirical methodology

4.1 Clustering approach

To classification of countries in the aforementioned 3 clusters for the cost of living, government effectiveness, political regime, level of tourism specialisation and tourism competitiveness is based on the k -means clustering method (the level of development criterion has only 2 clusters and these are given by the United Nations). The k -means clustering approach aims to partition n observations (in our case countries) into k clusters in which each observation belongs to the cluster with the nearest mean, serving as a prototype of the cluster.

Specifically, given a set of observations $(x_1, x_2, \dots, x - n)$, where each observation is a d -dimensional real vector, k -means clustering aims to partition the n observations into $k(n)$ sets $\mathbf{S} = \{S_1, S_2, \dots, S_k\}$ so as to minimize the within-cluster sum of squares (WCSS). In other

words, its objective is to find:

$$\arg \min_S \sum_{i=1}^k \sum_{x \in S_i} |||x - \mu_i|||^2 \quad (3)$$

where μ_i is the mean of points in S_i .

Our results presented here are based on $k(n)=3$ set, since this number resulted in an ample amount of countries (and therefore observations to perform our analysis) in each set/cluster. However, these results remain robust to alternative values of sets/clusters, such as 2 or 4. The latter results are available upon request.

4.2 Panel VAR approach

The panel VAR methodology combines the traditional VAR approach, which treats all the variables in the system as endogenous, with the panel-data approach, which allows for unobserved individual heterogeneity. In its general form, our model can be written as follows:

$$\Delta \ln Y_{it} = A_0 + A_1 \Delta \ln Y_{it-j} + A_2 X_{it} + \mu_i + \lambda_t + \varepsilon_{it} \quad (4)$$

where Y_{it} is a vector of our key variables: tourism income and economic growth. The autoregressive structure allows all endogenous variables to enter the model with a number of j lags. X_{it} is a vector of the exogenous variables, which are used as control variables, comprising: (i) labour force participation rate, capturing labour input, (ii) gross fixed capital formation as a % of GDP, measuring capital input, and (iii) imports plus exports over GDP, capturing the degree of openness. The data for the exogenous variables have been obtained from the World Development Indicators database.

The advantage of the panel VAR is the same as the advantage of any panel approach; i.e., it allows for the explicit inclusion of a fixed effect in the model, denoted μ_i , which captures all unobservable time-invariant factors at a country level. This is important for our purposes as the inclusion of these fixed effects allows each country to have a country specific level of each of the factors in the model, and, in addition, to capture other time-invariant factors, such as country size and number of heritage sites. However, inclusion of fixed effects presents an estimation challenge, which arises in any model which includes lags of the dependent variables: the fixed effects are correlated with the regressors and, therefore, the mean-differencing procedure commonly used to eliminate fixed effects would create biased coefficients.

To avoid this problem we use forward mean-differencing, also referred to as the ‘Helmert procedure’ (Arellano and Bover, 1995). This procedure removes only the forward mean, i.e., the mean of all the future observations available for each country-year. This transformation preserves the orthogonality between transformed variables and lagged regressors, which allows us to use lagged regressors as instruments and estimate the coefficients by system GMM. In our case the model will be just identified because the number of regressors will equal the number of instruments; therefore, system GMM is numerically equivalent to equation-by-equation 2SLS. Our panel VAR estimation routine follows Love and Zicchino (2006) and Love and Rima (2014).

Another benefit of the panel data is that allows for common time effects, λ_t , which are added to model (4) to capture any global (macroeconomic) shocks that may affect all countries in the same way. For example, time effects capture common factors such as interest rates, spreads or global risk factors. To deal with the time effects, we time difference all the variables prior to inclusion in the model, which is equivalent to putting time dummies in the system.

Model 4 above is commonly referred to as reduced form, in a sense that each equation only contains lagged values of all other variables in the system. The prime benefit of the VAR system is that allows the evaluation of the effect of the orthogonal shocks i.e., the impact of a shock of one variable on another variable, while keeping all other variables constant. This is accomplished with the use of impulse-response functions, which identify the reaction of one variable to the innovations in another variable in the system, while holding all other shocks equal to zero. However, since (i) the actual variance-covariance matrix of the errors is unlikely to be diagonal (e.g. errors are correlated), (ii) the results of the panel Granger causality tests revealed heterogeneous results among our variables/clusters and (iii) given that any particular ordering of the variables in our PVAR model would be hard to justify, we use the generalised PVAR framework (in the spirit of Koop et al., 1996; Pesaran and Shin, 1998), in which forecast error variance decompositions are invariant to the ordering of the variables.

To analyze the impulse–response functions, and to evaluate their statistical significance we estimate their confidence intervals. Since the matrix of impulse-response functions is constructed from the estimated VAR coefficients, their standard errors need to be taken into account. We generate the confidence intervals for the generalised impulse responses using Monte Carlo simulations.

5 Empirical findings

We begin our analysis with the full sample results as these are illustrated in Figure 5. Our analysis is based on international tourism receipts as a proxy for tourism growth.

[Insert Figure 5 around here]

We observe that although there is a bidirectional relationship between the tourism industry and economic growth during the first four years, the relationship subsequently turns into economy-driven. Thus, for the full sample estimation our results mainly coincide with the EDTG hypothesis, which implies that it is the economic performance of the sample countries that drives their tourism sectors. Nevertheless, the consideration of the full sample can only lead us to drawing some tentative conclusions, as the special qualities of our sample countries remain unmasked. Therefore, it would be interesting to isolate their particular characteristics and examine each ones effect on the tourism-economy relationship.

Initially, we divide our full sample of countries on the basis of their cost of living and the results are presented in Figure 6.

[Insert Figure 6 around here]

We observe that it is the least expensive countries (Cost of Living cluster 1) that confirm the EDTG in the longer run. This is perhaps surprising given that we would expect that the countries with lower cost of living, which are mainly the less developed ones, would be more responsive to export activity. Yet, this can be explained by the structure of the tourism industry in these destinations i.e. the number of outsiders and the high level of leakages of tourism income from their local economies.

As Perez and Juaneda (2000) explain, package deals contract out mass tourism destinations, meaning that visitors purchase their transport–accommodation package at home. This inevitably confines spending at destinations to pocket money payments and decreases tourism income considerably. The fact though that the economy drives the tourism sector in these countries can be potentially explained by the fact that weaker economies have limited ability to exploit their resources or develop their infrastructure in order to support their home industries, including tourism.

In high–cost destination countries (cluster 3) exists an extremely short-lived bidirectional relationship. However, after two years we observe that there is no effect neither from tourism

to the economy nor the reverse. Nonetheless, it is reasonable to argue that high cost of living is mostly found in mature economies where tourism is a peripheral and not a core economic activity. For example, the tourism sector in the US is about 2.7% of the national income.

In contrast, in countries with moderate cost of living, we observe a clear bidirectional relationship. It should be underlined that a considerable number of the countries that comprise this cluster have popular tourism products (e.g. Croatia, Cyprus, Malta, Portugal and Spain) and tourism is an important industry for their economies. In particular, according to the World Travel and Tourism Council, the tourism industry in Croatia contributes 27.8% of its GDP, in Cyprus 20.6%, in Malta 25.5%, in Portugal 15.6% and in Spain 15.7%.

Overall, the results imply that the relationship between tourism and economic growth is influenced by the cost of living, which as mentioned previously reflects the price of the tourism product.

Our second classification is based on countries level of development. In this case, we have two sub-groups, namely developed and developing countries (see Figure 7).

[Insert Figure 7 around here]

For developed countries, we observe a short-lived bidirectional relationship, which fades out in the long run. In essence, we do not find evidence of any strong relationship between tourism and economic growth for this cluster of countries. Furthermore, in developing countries, we see again a short-lived bidirectional relationship; however, and in contrast to developed countries, this turns into an EDTG relationship, given that the responses of tourism receipts to economic growth shocks are persistent. Our finding does not offer support to the argument that the contribution of tourism to economic growth is greater for developing countries than it is for the developed ones (see Dritsakis, 2012).

Next, Figure 8 exhibits our findings with regards to government effectiveness.

[Insert Figure 8 around here]

Interestingly, we observe that in the two extremes, i.e. high and low levels of bureaucracy (cluster 3 and 1, respectively) the relationship between tourism and the economy in the first couple of years is bidirectional and thence turns into economic-driven. High levels of bureaucracy hinder economic activities and may exert a negative influence on various economic sectors, including tourism. Similarly, when the levels of bureaucracy are low, economic activity and investment are encouraged and facilitated by the state and thus, it makes sense to promote

tourism activity as well. Further, when government effectiveness is medium the relationship remains bidirectional throughout the whole study period.

As far as the influences of political regimes on the tourism-economy relationship are concerned, these are illustrated in Figure 9.

[Insert Figure 9 around here]

As can be seen in Figure 9, an EDTG relationship is witnessed in countries with authoritarian or hybrid regimes (cluster 1). The interpretation of such finding is twofold; first, it can be argued that in many instances authoritarian practices create a turbulent environment for economic activities and hence, for all economic sectors including tourism. This incurs in non-democratic regimes as governments often employ a rent-seeking behaviour to gain political support rather than providing public goods (Plümper and Martin, 2003).

Second, it has been established by the political economy literature that it is common for economies which lack democracy to be controlled by a single individual or a small group of individuals. Such power imbalances do not allow the economy to grow or to spread the benefits of economic activity across society due to corruption (de Vaal and Ebben, 2011; Drury et al., 2006; Mo, 2001). Thus, we maintain that the way that the economy is controlled in non-democratic states influences tourism growth.

In contrast, the clusters of countries with democracy (cluster 2) or full democracy (cluster 3) exhibit a bidirectional relationship, although this is short-lived for cluster 3. It is suggested that countries with either flawed or full democratic regimes are able to exploit the maximum capacity of their economies and consequently, are at a good position to support investment in their various sectors. Moreover, given that the benefits from each sector can be shared more fairly across society it is reasonable to argue that sectoral performance (in our case, tourism) could assist economic growth.

When considering tourism specialisation, defined as the number of WHS, we discern that regions of high or medium specialisation exhibit zero relationship between tourism and economic growth for most of our study frame, apart from the first few years of the impulse response period where a bidirectional relationship is evident (see Figure 10). In contrast, when tourism specialisation is low the bidirectional causality is witnessed for a short time period whereas in consecutive years the economy maintains the lead in the transmission of effects.

[Insert Figure 10 around here]

Hence, it appears that tourism specialisation exerts a quasi-opposite effect on destinations, a phenomenon for which might lie various explanations. First, we need to take into account the fact that it is the countries themselves that need to develop the nomination proposals for any site in their territory. Consequently, an inclusion to the list requires the use of resources (for conducting the necessary studies) and a certain level of government effectiveness and collaboration for meeting the nomination criteria (i.e. presenting a holistic approach as required by UNESCO). Given this set of circumstances, it can be argued that it is often the more developed and government efficient countries, which tend to achieve the WHS status for a higher number of sites as compared to the less developed ones (for instance, there are 7 WHS in Egypt as compared to 41 and 40 sites in France and Germany, respectively).

Second, although WHS may also include places of natural significance, the vast majority of listed sites are of cultural character (i.e. 802 out of 1031). There are some destinations with a low level of tourism specialisation which tend to be less popular for their cultural offer and more famous for their exoticism (for instance, the Bahamas, Dominican Republic, Mauritius and Seychelles). The so-called sea-sun-sand tourism offer in these regions might stimulate some wider economic responses that are nonetheless short-lived, perhaps due to the low spending character of sea-sun-sand visitors (Taylor et al., 1993).

Third, some of the countries in the low specialisation cluster have a significantly less developed tourism sector or significant geopolitical turbulence, which explains the fact that tourism does not affect their economic growth significantly (for example, Angola, Kazakhstan and Sierra Leone).

Finally, when we take into account the tourism competitiveness index we observe that the results resemble those from the cost of living, political regime and tourism specialisation clusters (see Figure 11), which provides an additional robustness to our existing findings.

[Insert Figure 11 around here]

6 Summary and concluding remarks

Existing empirical evidence on the tourism-economic growth relationship has been inconclusive so far and has led to various, often contradictory, interpretations of their causal direction of effects. This might be the result of focusing on a single country or cluster of countries by using panel regression models. We suggest that panel regression can be rather problematic when addressing this question, as the existence of causal effects is considered given. In contrast, this

paper employs Panel VAR analysis, where the direction of effects is not *a priori* selected but rather allows for both variables to interact simultaneously.

At the same time, this study seeks to evaluate the said relationship not by grouping countries based on a single characteristic but rather, by considering a set of six different criteria that influence the tourism-economy dynamics. Our broad sample of 113 countries allows us to make generalisations more securely, whereas the use of three different proxies for tourism growth i.e. international tourism receipts, tourist arrivals, and tourism expenditure, as percentages of GDP, adds to the robustness of our findings.

The results of this study cannot support the existence of a tourism-led economic growth relationship, in neither mature nor emerging economies. Rather, tourism sectors in developing countries appear to be economy-driven - a finding that rejects the idea of tourism as a poverty alleviation driver. In mature economies, the causal hypotheses are also rejected, as the effects between the two factors are negligible. Interestingly, countries with highly competitive tourism product, where we would expect a more dynamic role for tourism, exhibit no long-term effects. The only exception is for countries with moderate competitiveness levels, where a mutual causal relationship is observed. Similarly, countries with democratic regimes and long-term political stability, which could encourage tourism, show no causal effects between the two factors.

Such findings imply that policy makers in developing and less tourism-competitive countries could either seek to restructure their tourism sector by decreasing tourism income leakages or place more emphasis on other sectors when designing policies for economic development. In addition, those developing countries with significant tourism activity could apply a safety net to their tourism industry with the view to isolate influences of the economy, in cases of negative economic shocks.

At the same time, highly competitive and mature economies can develop tourism policies, which would be independent from their economic activity, given the neutral relationship between tourism and economic growth. Those who should pay more attention to their tourism sector are the countries that exhibit bidirectional causalities i.e. countries with moderate cost of living, government efficiency and competitive levels, as there exists the potential for tourism to foster economic growth.

Finally, an interesting avenue for further research is to investigate the potential indirect relationship between tourism and economic growth with the use of PVAR models and multiple endogenous variables (such as employment or infrastructure).

The numbers in brackets denote p -values. The LLC and IPS tests are performed using the Newey–West bandwidth selection with Barlett Kernel, and the Schwartz Bayesian Criterion is used to determine to optimal lag length. GR at the end of the acronym indicates growth rates. *, ** and *** indicate rejection of the null hypothesis at the 10, 5 and 1 percent levels of significance, respectively.
