Abstract

This paper examines the relationship between investments and uncertainty for the US economy, as the latter is approximated by consumer sentiment, purchasing managers’ prospects and economic policy uncertainty. Contrary to the existing literature, we provide evidence that this relationship is time-varying. The time variation is attributed to the observed temporal replacement effect between private and public investments. Furthermore, we show that there are two distinct correlation regimes in this relationship and unless we concentrate on the two regimes, we cannot fully unravel the real link between uncertainty and investments. Finally, we examine whether the use of two correlation regimes provides better forecasts of investments compared to the use of the uncertainty indices alone. The forecasting exercise reveals that the use of correlation regimes provides statistically superior out-of-sample forecasts.

1. Introduction

Politicians and international institutions make decisions that alter the way in which economies operate and interact. This is particularly relevant in the light of the recent recession and financial crisis, the European sovereign debt crisis and the rising US fiscal deficit, when politicians assumed a bold role in stabilizing and shaping the world economy. In this regard, there is a significant degree of uncertainty as to what tools policy makers and institutions will use, what impact these decisions will have on economy and how timely they are going to be.

Evidence suggests that when faced with such uncertainty, US corporations choose to reduce capital investment (Rodrick 1991; Bloom et al., 2007; Baum et al., 2008). Usual is also the case where the press media attribute a reduction in corporate investment partly to increased policy uncertainty. In the same context, both European Investment Bank (2013) and IMF (2015) conclude that uncertainty, both economic and policy, has been the most important immediate cause of low investment in Europe. They report that sectors of the economy that are more sensitive to uncertainty experience a larger fall in investment relative to less sensitive sectors during times of high economy wide uncertainty.

Furthermore, several theoretical studies have established mechanisms through which higher uncertainty may cause lower investment rates. First, Bernanke (1983) and Rodrik (1991), among others, argue that if investment projects are not fully reversible, uncertainty will increase the benefit of the option to wait until more information of the projects is revealed. Second, uncertainty exaggerates the costs of external financing by increasing default risk (e.g. Gilchrist et al., 2014) or the equity risk premium (Pástor and Veronesi, 2013) which can lead to investment contraction. Overall, this strand of the literature supports the current census of the constant linkage between higher uncertainty and investment decline.

In empirical terms, the work of Aizenman et al. (1993), Episcopos (1995) and Asteriou et al. (2005) provide evidence of a significant negative relationship between uncertainty and investment, thereby confirming the aforementioned theoretical studies.

---

1 See, for example, “Investment Falls Off a Cliff: U.S. Companies Cut Spending Plans Amid Fiscal and Economic Uncertainty” (Wall Street Journal, November 19, 2012).
2 For a complete list of articles relating economic policy uncertainty with economic performance see: http://www.policyuncertainty.com/media.html.
Despite a plethora of evidence on the effects of uncertainty on fixed assets investments, none of the studies have examined the potential time-varying relationship between the aforementioned variables. The assumption of a time-varying correlation between uncertainty and various macroeconomic variables has only recently received substantial attention in the literature (for instance, relating policy uncertainty and stock market returns – see, Antonakakis et al., 2013; Kang and Ratti, 2013; Lean and Nguyen, 2014; Alexopoulos and Cohen, 2015, among others). However, there is still a growing interest in understanding the real economic effects of uncertainty. This study adds to this growing literature showing that the use of time-varying correlation unravels the full dynamics of the relationship between investments and uncertainty.

In studying the relationship between uncertainty and investments, there is the very important issue of how to measure and quantify uncertainty. A task which is rather complicated. Several data sources and a wide range of indicators have been generally used in the literature to capture uncertainty, including data from consumer and business surveys. Verifying whether these data and indicators capture what they are supposed to capture is an important issue. Thus, this study apart from the examination of the uncertainty and investments in a time-varying environment, it also attempts to provide an answer as to which uncertainty measure is the best leading indicator for the US investments.

Overall, the paper contributes to the literature of uncertainty and investments, focusing on the interrelations between different types of uncertainty and fixed assets investments rather than stock market investments, in the US economy. We take a disaggregate view on private and governmental (or public) investment, using three potential sources of uncertainty, namely, consumer, business and policy uncertainty. To do so, we make use of the consumer sentiment indicator, the purchasing managers’ index and the recently developed economic policy uncertainty index of Baker et al. (2013). Finally, we produce a forecasting exercise in order to establish which uncertainty indicator(s) can produce better forecasts of fixed assets investments.

The results show that the relationship is indeed time-varying and there are two distinct correlation regimes. Furthermore, we report that Consumer Sentiment Index is the best leading indicator for the US investment, followed by Policy Uncertainty Index. More importantly, we reveal that the incorporation of the time-varying
correlation effects provide statistically superior out-of-sample forecasts of US investments.

Our investigation, apart from the obvious policy implications that are particularly important in the current recession phase of global economy, provides a yardstick for nowcasters and forecasters that seek a well-chosen leading indicator for the US investments.

The remaining of the paper is structured as follows. In section 2 we describe the data used in this study. Section 3 illustrates the methodology used for the estimation of the time-varying correlation. Section 4 analyses the empirical findings and Section 5 concludes the study.

2. Data description

The employed data include the consumer sentiment indicator (CSI), purchasing managers’ index (PMI), the economic policy uncertainty index (PUI), which represent our uncertainty indices, and the gross fixed capital formation as a percentage of GDP (Investments), which approximates the level of US investments. We disentangle the total investments into private and governmental, in order to examine the potential heterogeneous attitude of uncertainty on the private and the public sector’s investment activity. Our sample runs from 1985:Q1 to 2014:Q3. Investments are in constant terms. Data on the CSI and PMI are obtained from Federal Reserve Economic Data, the Investments are obtained from Datastream® and PUI is obtained from Baker et al. (2013). Figure 1 shows the evolution of the series.

From Figure 1, panel A, we observe that the CSI and PMI indices tend to fluctuate in parallel, whereas the opposite holds for the PUI index. This is particularly noticeable during the early-2000, as well as, during the Great Recession of 2007-2009.

An analogous pattern is also met after 2012, as the declining trend of PUI is supported by a rebound of real economy sentiment indicators, i.e. CSI and PMI. Still following the EMU sovereign crisis right after the 2007-2009 US recession, real economy sentiment did not follow the rising economic policy uncertainty.

This may suggest that the real sector uncertainty was resolved fairly quickly after the end of the Great Recession, while economic policy uncertainty persisted until 2012, possibly mirroring EMU uncertainty and an anaemic growth of the US economy. Another interesting observation is that during economic recessions we
observe the opposite behaviour between the private and public investments, which is suggestive of a substitution effect between these spending items.

3. Methodology

In order to investigate the time-varying correlation between investment and sentiment indicators, we define a bivariate framework for the dynamic estimation of their variance-covariance matrix. The \( \mathbf{y}_t = \begin{pmatrix} y_{t}^{(n)} \\ x_{t}^{(m)} \end{pmatrix} \) vector denotes the ratio of investment to GDP, \( y_{t}^{(n)} = \frac{GFCF_{t}^{(n)}}{GDP_{t}} \), and the sentiment indicator, \( x_{t}^{(m)} \), at a quarterly frequency \( t \). For \( n = 1,2,3 \), the \( GFCF_{t}^{(n)} \) variable expresses the total, governmental and private investments, respectively. For \( m = 1,2,3 \), the sentiment indicators are the CSI, PMI and PUI indices, respectively\(^3\). The sentiment indicators are available in a monthly frequency. The PMI, ESI and CSI indices are computed as the moving average of the six most recent monthly observations. Often to go from monthly to quarterly frequency, it is preferable to just take the last monthly observation in the quarter. However, due to the highly volatile nature of the sentiment series we choose the moving average approach, which reduces the volatility, while maintaining the information extracted from the series. The lag order of \( x_{t-i}^{(m)} \) is the \( i \) that maximizes the cross correlation between \( y_{t}^{(n)} \) and \( x_{t-i}^{(m)} \). The proposed framework is:

\[
\mathbf{y}_t = \beta_0 + \mathbf{e}_t, \\
\mathbf{e}_t = \mathbf{H}_{t}^{1/2} \mathbf{z}_t, \\
\mathbf{z}_t \sim N(\mathbf{0}, \mathbf{I}),
\]

where \( \beta_0 \) denotes the mean of \( \mathbf{y}_t \), and \( \mathbf{z}_t \) is a bivariate normally distributed process with \( E(\mathbf{z}_t) = \mathbf{0} \) and \( E(\mathbf{z}_t \mathbf{z}_t') = \mathbf{I} \). The demeaned vector of \( \mathbf{y}_t \), or \( \mathbf{e}_t \), has a conditional variance-covariance matrix \( \mathbf{H}_t \). The variance-covariance matrix \( \mathbf{H}_t \) is estimated in a Diag-VECH framework according to Bollerslev’s et al. (1988) specification\(^4\):

\(^3\) All variables are stationary and the test statistics are available upon request.

\(^4\) The \textit{vech} (.) operator stacks the columns of an \( (n \times n) \) square matrix from the diagonal downwards in an \( (n(n+1)/2) \times 1 \) vector. The symbol \( \circ \) denotes the Hadamard (elementwise) product.
\[ \text{vech} \left( \mathbf{H}_t \right) = \text{vech} \left( \mathbf{A}_0 \right) + \sum_{j=1}^{q} \left( \text{vech} \left( \mathbf{A}_j \right) \text{vech} \left( \mathbf{e}_{t-j} \mathbf{e}_{t-j}' \right) \right) + \sum_{j=1}^{p} \left( \text{vech} \left( \mathbf{B}_j \right) \text{vech} \left( \mathbf{H}_{t-j} \right) \right). \] (2)

According to Degiannakis et al. (2013) we do not include lags of the endogenous variables in the conditional mean, as the non-diagonal elements of the variance-covariance matrix would express the time-varying correlation of the residuals. Thus, we would then have estimated the time-varying correlation of the unexplained part of the endogenous variables.

The time varying correlation between \( y^{(n)}_t \) and \( x^{(m)}_t \) is estimated as:

\[ \rho_{(n,m)}^{t} = \frac{\sigma_{y^{(n)}_t x^{(m)}_t}}{\sqrt{\sigma_{y^{(n)}_t} \sigma_{x^{(m)}_t}}}, \] (3)

where \( \sigma_{y^{(n)}_t}^{2} \) and \( \sigma_{x^{(m)}_t}^{2} \) are the diagonal elements of \( \mathbf{H}_t \), and \( \sigma_{y^{(n)}_t x^{(m)}_t}^{(n,m)} \) is the non-diagonal element of \( \mathbf{H}_t \).

An asymmetric form of the Diag-VECH model, a leptokurtically distributed \( z_t \) process, and the lag orders \( p, q \) have been investigated according to the standard statistical criteria. The Diag-VECH specification is preferable compared to models with large time varying covariance matrices; i.e. Engle's (2002) DCC model. Moreover, it involves the estimation of less number of parameters than other multivariate GARCH models; i.e. Engle and Kroner's (1995) BEKK model, Engle's et al. (1986) VECH model, etc. For technical information see Xekalaki and Degiannakis (2010).

4. Results

4.1. Time-varying correlations

The results of the time-varying correlations between investments and uncertainty indicators are shown in Figure 2. Given the fact that higher CSI/PMI reflects lower uncertainty, whereas the reverse holds true for PUI, we rely on the theoretical evidence of a positive (negative) correlation between investments and CSI and PMI (PUI).

[FIGURE 2 HERE]

Contrary to both the existing theoretical and empirical evidence, we observe that all correlations fluctuate in both the negative and positive areas and they are, indeed, time-varying. It is clear that two regimes exist in the relationship between the
uncertainty indicators and investments. This holds for all three uncertainty indicators. Thus, examining the aforementioned relationship in a static framework masks some important regime changes, which could provide additional feedback to policy makers.

Another interesting observation is that these correlations exhibit heterogeneous patterns for different uncertainty indicators. For instance, looking at the total investments (top panel) during the 1990s recession, we notice that correlations with the PMI and PUI are negative, whereas a zero correlation exists with CSI. Moreover, during the early 2000 recession, correlations are all positive. It is only during tranquil periods and the Great Recession that the expected positive (negative) correlations with the CSI and PMI (PUI) are reported (Figure 2).

Turning our attention to the correlations for the governmental and private investments, the following regularities are observed. First, the governmental correlations resemble the patterns of the total investments correlations, which is expected as the main component of investments is the private one. Second, there is evidence of a replacement effect between governmental and private investments. For instance, the correlations between CSI and governmental (private) investments are mainly negative (positive). The reverse holds true for the PUI. This replacement effect may suggest a more active Keynesian countercyclical public investment policy stance aiming to avoid recessionary phases of the economic circle. The last observation from the middle and lower panels of Figure 2 is that the picture is quite unclear in the case of PMI which may suggest that PMI is not a credible leading indicator for the US investments.

4.2. Time-varying correlation regimes and the best leading indicator

In an attempt to identify the best leading indicator for the US investments and check robustness of previous findings the following model is estimated:

\[
y_{i}^{(n)} = \gamma_{0} + \gamma_{1} d(\rho_{i}^{(n,m)} > 0) + \gamma_{2} x_{i}^{(n)} + \gamma_{3} d(\rho_{i}^{(n,m)} > 0) x_{i}^{(n)} + \epsilon_{i},
\]

where \( \epsilon_{i} \sim N(0, \sigma_{\epsilon}^{2}) \) and \( d(\rho_{i}^{(n,m)} > 0) \) is a dummy variable that takes the value of one when the time-varying correlation is positive and the value of zero otherwise. The use of a dummy variable, aims to quantify the differential inter-linkages between uncertainty and investment as implied by the two different regimes previously observed (Figure 2). The results are shown in Table 1.

[TABLE 1 HERE]
From Eq. (4) we notice that the use of two regimes offers significant information for the US investments (see Table 1). More specifically, the interaction terms provide evidence of a change in the relationship between uncertainty and investments, where in regime 1 (i.e. positive correlation) the effect of uncertainty on investments is positive (i.e. $\gamma_2 + \gamma_3$), whereas in regime 2 (i.e. negative correlation) the effect is negative (i.e. $\gamma_2$). Finally, the adjusted coefficient of determination suggests that the best leading indicator is CSI, followed by PUI, whereas PMI performs poorly (as also depicted by Figure 2).

In order to verify further the aforementioned results we proceed with an out-of-sample forecasting exercise based on Eq. (4). More specifically, the scope of the forecasting exercise is twofold. First, to establish whether the use of the two regimes in the time-varying correlation between uncertainty and investments offers a better predictive ability compared to the direct effects of the uncertainty on investments. Second, whether CSI and PUI are indeed the best leading indicators for the US investments.

Eq. (4) is estimated in its full version incorporating the time-varying correlation effect, as well as in its nested version, with \( \gamma_1 = 0 \) and \( \gamma_3 = 0 \), taking into consideration only the information provided by the uncertainty indicators. The initial training period of the models is \( T \approx 60 \) quarters, i.e. from 1985Q1 until 1999Q4. For the period 2000Q1 to 2014Q3 (i.e. the remaining \( T \approx 59 \) quarters), the one-quarter-ahead forecasts of \( y_{(n)} \), for \( n = 1, 2, 3 \), are estimated. In order to proceed to the first out-of-sample forecast (i.e. \( t+1 \) forecast or 2000Q1) we train the models using the initial 60 quarters. For each following out-of-sample forecast we add to the training period an additional quarter. For example, for the \( t+2 \) forecast we use \( T + 1 \) quarters. Thus, at each quarter, the models are re-estimated based on all past information set available. The forecasting accuracy of the models is gauged using three established loss functions, namely the MSE, MAE and MAPE, as shown in Table 2.

[TABLE 2 HERE]

Table 3 reports the three forecasting evaluation criteria for the two different forecasting models, whereas Figure 3 depicts the actual and forecasted investments. The results provide evidence that the forecasts with the CSI outperform these produced by PMI or PUI for all cases but the government investments. Interestingly
enough, it is PMI that generates the best forecasts in this instance. More importantly, it is evident that the use of correlation regimes improves the forecasting accuracy in all cases. A close competitor of CSI is PUI, where in most cases (apart from the governmental investments) it seems to provide the second best forecasts. Thus, we maintain the CSI is indeed the best leading indicator, followed by PUI. Finally, we provide evidence that the use of correlation regimes is capable of significantly improving the forecasting accuracy.

[TABLE 3 HERE]

[FIGURE 3 HERE]

In order to investigate further i) which leading indicator and ii) whether the time-varying correlation effect provide statistically more accurate forecasts, we utilize the Model Confidence Set (MCS) procedure of Hansen et al. (2011). The MCS procedure defines the models that perform the best predictions, where best is defined in terms of the MSE, MAE and MAPE loss functions. We compare the prediction accuracy of the initial set of the six models for each $y^{(n)}_t$. The Eq. (4) in its full and nested version for the three leading indicators defines the set of the six models. For $M^0$ defining the initial set of the six models, $L_{i,t}$ denoting the loss function of model $i$ at quarter $t$, and $d_{i,j,t} = L_{i,t} - L_{j,t}$ is the evaluation differential for $i, j \in M^0$, the hypotheses that are being tested are:

$$H_{0,M^0} : E(d_{i,j,t}) = 0$$

(5)

for $\forall i, j \in M$, $M \subset M^0$ against the alternative $H_{1,M^0} : E(d_{i,j,t}) \neq 0$ for some $i, j \in M$. The prediction accuracy of $M^0$ set of models is investigated, at a predefined level of significance, and explores which models survive the elimination algorithm. The elimination algorithm based on an equivalence test and an elimination rule, employs the equivalence test for investigating the $H_{0,M^0}$ for $\forall M \subset M^0$ and the elimination rule to identify the model $i$ to be removed from $M$ in the case that $H_{0,M^0}$ is rejected.

Table 4 presents the MCS $p$-values. The MCS $p$-values are analogous to that of a classical $p$-value; a $(1 - a)$ confidence interval that contains the true parameter with a probability no less than $(1 - a)$. The MSC $p$-values clearly suggest that i) the
CSI leading indicator as well as ii) the incorporation of the time-varying correlation effects provide statistically superior forecasts of US investments.

[TABLE 4 HERE]

5. Conclusion

The aim of this study is to assess empirically for the first time the relationship between uncertainty and investments from a macroeconomic perspective for the case of US economy. Three different sources of uncertainty, namely, the CSI, PMI and PUI are employed. The findings show that the relationship between investments and uncertainty does not always follow the general anecdotal temporal principles of positive and negative correlations depending on the source of uncertainty. This is an important finding, which provides evidence that the relationship between investment and uncertainty is rather complex and it is both time depended, as well as, driven by economic cycles. Furthermore, we reveal a countercyclical behavior of the governmental investments, whereas a pro-cyclical behavior is observed for the private investments. This differential behavior is informative of a significant substitution–crowding out effect between these different instruments. Finally, our findings suggest that CSI and PUI are better leading indicators for the US investments, rather than the PMI. Finally, the MSC test provides evidence that the CSI uncertainty measure with the incorporation of the time-varying correlation effects provide statistically superior forecasts of total, private and governmental US investments.
