This Draft: September, 2016

Abstract

Differences-in-Differences (DID) is one of the most widely used identification strategies in applied economics. However, how to draw inferences in DID models when there are few treated groups remains an open question. We show that the usual inference methods used in DID models might not perform well when there are few treated groups and errors are heteroskedastic. In particular, when there is variation in the number of observations per group, inference methods designed to work when there are few treated groups tend to (under-) over-reject the null hypothesis when the treated groups are (large) small relative to the control groups. We provide evidence from Monte Carlo simulations and from placebo DID regressions with the American Community Survey (ACS) and the Current Population Survey (CPS) datasets to show that this problem is relevant even in datasets with large numbers of observations per group. We then derive an alternative inference method that provides accurate hypothesis testing in situations where there are few treated groups (or even just one) and many control groups in the presence of heteroskedasticity. Our method assumes that we can model the heteroskedasticity of a linear combination of the errors. We show that this assumption can be satisfied without imposing strong assumptions on the errors in common DID applications. Importantly, we do not need to specify the structure of the serial correlation of the errors. Our inference method can also be combined with feasible generalized least square (FGLS) estimation. This way, it is possible to attain an asymptotically uniformly most powerful (UMP) test if the FGLS t-test is asymptotically UMP, while still provide a test with correct size if the serial correlation is misspecified. With many pre-treatment periods, we provide an alternative inference method that relies on strict stationarity and ergodicity of the time series instead of relying on the correct specification of the heteroskedasticity. Finally, we extend our inference methods to linear factor models when there are few treated groups.

Keywords: differences-in-differences; inference; heteroskedasticity; clustering; few clusters; bootstrap; randomization inference; linear factor model

1 Introduction

Differences-in-Differences (DID) is one of the most widely used identification strategies in applied economics. However, inference in DID models is complicated by the fact that residuals might exhibit intra-group and serial correlations.\(^1\) Not taking these problems into account can lead to severe underestimation of the DID standard errors, as highlighted in Bertrand et al. (2004). Still, there is as yet no unified approach to dealing with this problem. As stated in Angrist and Pischke (2009), “there are a number of ways to do this [deal with the serial correlation problem], not all equally effective in all situations. It seems fair to say that the question of how best to approach the serial correlation problem is currently under study, and a consensus has not yet emerged.”

One of the most common solutions to this problem is to use the cluster-robust variance estimator (CRVE) at the group level.\(^2\) By clustering at the group level, we allow for unrestricted correlation in the within-group errors. More specifically, we allow not only for correlation in the errors of observations in the same group x time, but also for correlation in errors of observations in the same group at different time periods. One important advantage of CRVE is that it also allows for unrestricted heteroskedasticity. The variance of the DID estimator can be divided into two components: one related to the variance of the treated groups and another one related to the variance of the control groups. The CRVE takes heteroskedasticity into account by essentially estimating the variance separately for the treated and for the control groups. Bertrand et al. (2004) show that CRVE and pairs-bootstrap at the group level work well when the number of groups is large.\(^3\) Even when there are only a small number of groups, it might still be possible to obtain tests with correct size even with unrestricted heteroskedasticity (for example, Cameron et al. (2008), Brewer et al. (2013), Canay et al. (2014), Ibragimov and Müller (2013), and MacKinnon and Webb (2015a)). However, these inference methods will eventually fail when the proportion of treated groups goes to zero or one, even if there are many groups in total (MacKinnon and Webb (2015b)). The problem is that, with a small number of treated groups, it is hard to estimate the variance component related to the treated groups using only the residuals of the treated group. In the polar case where there is only one treated group, the CRVE estimate of this component of the variance would be identical to zero.\(^4\)

---

\(^1\) We refer to “group” as the unit level that is treated. In typical applications it stands for states, counties, or countries.

\(^2\) The CRVE was developed by Liang and Zeger (1986). We can think of this method as a generalization of the heterocedasticity-robust variance matrix due to White (1980).

\(^3\) Wooldridge (2003) provides an overview of cluster-sample methods in linear models. The author shows that CRVE provides valid inference when the number of groups increases and groups sizes are fixed.

\(^4\) Another alternative presented by Bertrand et al. (2004) is to collapse the pre- and post-information. This approach would take care of the auto-correlation problem. However, in order to allow for heteroskedasticity, one would have to use robust standard errors, in which case this method would also fail when there are few treated groups.
An alternative when there are few treated groups is to use information from the control groups in order to estimate the component of the variance related to the treated groups. Donald and Lang (2007), henceforth DL, use small sample inference procedures on the group x time DID aggregate model relying on normality and serially uncorrelated errors.\(^5\) Two alternative methods relax the normality assumption and allow unrestricted serial correlation: Conley and Taber (2011), henceforth CT, and cluster residual bootstrap, analyzed by Cameron et al. (2008). While these methods work even when there is only one treated group, they all rely on the assumption that errors (or a linear combination of the errors) are homoskedastic, so that we can use the residuals of the control groups to assess the distribution of the errors of the treated groups.\(^6\) However, this homoskedasticity assumption might be very restrictive in DID applications. In particular, errors in the group x time DID aggregate model should be inherently heteroskedastic when there is variation in the numbers of observations used to calculate each group x time average.\(^7\)

In this paper, we first show that usual inference methods used in DID models might not perform well when there are only a few treated groups. Methods that allow for unrestricted heteroskedasticity do not work because they estimate the component of the variance related to the treated groups based on few observations. Also, alternative methods that use information from the control groups will not work properly in the presence of heteroskedasticity. In the particular case in which the number of observations per group varies, these methods tend to (under-) over-reject the null hypothesis when the number of observations in the treated groups is (large) small relative to the number of observations in the control groups. The problem is that variation in the number of observations per group invalidates the homoskedasticity assumption, because larger groups tend to have lower variance. The intuition of this result was already articulated in Assuncao and Ferman (2015) in an application of CT.\(^8\) We formalize this idea and derive conditions under which this problem would be more relevant. In particular, we show that increasing the number of observations per group has little impact on the heteroskedasticity when the intra-group correlation approaches zero. In Monte Carlo simulations and simulations with the American Community Survey (ACS) and the Current Population Survey (CPS), we provide evidence that this problem can be relevant even in datasets with very large numbers of observations per group. Therefore, a large number of individual observations per group should not provide a reasonable justification for homoskedasticity in the group x time model.

\(^5\) Pengyuan et al. (2013) relax the normality assumption for the 2-periods case using a flexible skew-t distribution family to model group time effects.

\(^6\) CT present in their online Appendix an alternative method when there is heteroskedasticity generated by population sizes. Their method, however, requires the full specification of the variance/covariance matrix.

\(^7\) In case of individual-level data, all these methods require some kind of aggregation at the group x time level. Therefore, this problem is relevant whether one has individual-level or aggregate data.

\(^8\) Assuncao and Ferman (2015) exclude the comparison of placebo estimates when the placebo treated group is much smaller than the original treated group.
We then derive an alternative method for inference when there are only few treated groups (or even just one) and errors are heteroskedastic. The main assumption is that we can model the heteroskedasticity of a linear combination of the errors.\(^9\) Under this assumption, we can re-scale the residuals of the control groups using the (estimated) heteroskedasticity structure so that they become informative about the distribution of the errors of the treated groups. Importantly, by focusing on a linear combination of the errors, we do not need to specify the serial correlation structure and we also circumvent the incidental parameter problem caused by the estimation of group fixed effects with a finite number of time periods. We show that a cluster residual bootstrap with this heteroskedasticity correction provides valid hypothesis testing asymptotically when the number of control groups goes to infinity, even when there is only one treated group. Our Monte Carlo simulations and simulations with real datasets suggest that our method provides reliable hypothesis testing when there are around 25 groups in total (1 treated and 24 controls).

Our inference method can also be combined with feasible generalized least squares (FGLS) estimation. The use of FGLS to improve efficiency of the DID estimator has been proposed by Hausman and Kuersteiner (2008), Hansen (2007), and Brewer et al. (2013). One important challenge for implementing a FGLS estimator in the DID setting is that sample analogs for the variance/covariance matrix parameters will be biased when the number of periods is fixed. While these papers provide bias-corrected estimators for the parameters of the variance/covariance matrix, they rely on strong assumptions on the structure of the errors, including homoskedasticity.\(^10\) Following Wooldridge (2003), Hansen (2007) and Brewer et al. (2013) combine their FGLS estimators with cluster-robust inference. This way, their inference is robust to misspecification in either the serial correlation or the heteroskedasticity structures. However, with few treated groups the use of CRVE would not work. In this case, we show that it is possible to combine FGLS estimation with our inference method. If the FGLS estimator is asymptotically equivalent to the GLS estimator and errors are normally distributed, then we show that our test is asymptotically uniformly most powerful (UMP) when the number of control groups goes to infinity. If, however, we have misspecification of the serial correlation, the estimators of the serial correlation parameters are inconsistent, or we do not have normally, then a t-test based on the FGLS estimator would not be valid, while our test would still provide the correct size. Therefore, our method provides an important safeguard for the use of FGLS estimation in DID applications with few treated groups.

\(^9\)While our method is more general, this assumption would be satisfied in the particular example in which the heteroskedasticity is generated by variation in the number of observations per group.

\(^10\)Hausman and Kuersteiner (2008) assume that the variance/covariance matrix is block diagonal with the same block for each group, while Hansen (2007) and Brewer et al. (2013) assume homoskedasticity and constant AR coefficients.
With only one treated group, the assumption that we can model the heteroskedasticity of a linear combination of the errors can only be relaxed if we impose instead restrictions on the intra-group correlation. If we assume that, for each group, errors are strictly stationary and ergodic, then we show that it is possible to apply Andrews’ (2003) end-of-sample instability test to a transformation of the DID model for the case with many pre-treatment and a fixed number of post-treatment periods. This approach works even when there is only one treated and one control group. We also consider the use of linear factor models for estimation of regional policies treatment effects, as suggested by Gobillon and Magnac (2013). This approach requires both large $N$ and $T$, but it allows selection into treatment to freely depend on unobserved heterogeneity terms. We show that our inference methods can be extended to linear factor models when there are only a few treated groups. Another estimation method for the case with few treated groups is the synthetic control (SC) estimator (Abadie and Gardeazabal (2003) and Abadie et al. (2010)). Ferman and Pinto (2016) derive conditions under which the permutation test proposed in Abadie et al. (2010) is asymptotically valid in the presence of heteroskedasticity. In addition to requiring restrictions on the time series that transitory shocks are stationary, we show that the permutation test would only be valid if the SC weights converge in probability to weights that satisfy the SC assumptions, which will not generally be the case.$^{11,12}$

Our inference method is related to the Randomization Inference (RI) approach proposed by Fisher (1935). In this approach, one uses a permutation test that calculates the test statistic under all possible combinations of treatment assignment, and rejects the null if the observed realization in the actual experiment is extreme enough. The RI approach assumes that treatment assignment is the only stochastic element of the model. In this case, RI provides exact hypothesis testing regardless of the characteristics of the residuals (Lehmann and Romano (2008)). We argue that the RI approach would not provide a satisfactory solution to our problem. First, a permutation test would not provide valid inference if the assignment mechanism is unknown.$^{13}$ Moreover, even under random assignment, a permutation test would only remain valid for unconditional tests (that is, before we know which groups were treated). However, as suggested in McCullagh (1992), unconditional tests can be “inappropriate and possibly misleading for hypotheses concerning the data at hand”, while “conditional probability calculation often provides an answer to which no right-thinking person

---

$^{11}$In a previous version of this paper, Ferman and Pinto (2015) show that the permutation test proposed in Abadie et al. (2010) would be asymptotically valid under heteroskedasticity if the SC weights converge in probability to weights that satisfy the SC assumptions and the transitory shocks are stationary. This discussion is now presented in Ferman and Pinto (2016).

$^{12}$Powell (2016) and Carvalho et al. (2015) suggest alternative estimation methods for comparative studies that also provides valid inference with one treated group. However, they rely on both the number of pre- and post-treatment periods going to infinity.

$^{13}$This would be the case if, for example, larger states are more likely to switch policies. Rosenbaum (2002) proposes a method to estimate the assignment mechanism under selection on observables. However, with few treated groups and many control groups, it would not be possible to reliably estimate this assignment mechanism. Note that it is possible that the DID identification assumptions are valid even when the assignment mechanism is not uniform.
In our setting, once one knows that the treated groups are (large) small relative to the control groups, then one should know that a permutation test that does not take this information into account would (under-) over-reject the null when the null is true. Therefore, such test would not have the correct size conditional on the data at hand, providing inappropriate hypothesis testing. One alternative solution would be to follow Canay et al. (2014). In their setting, they show that it would be possible to incorporate information on (for example) group sizes if one had functions of the data that have the same limiting distribution under the null hypothesis in all permutations. Canay et al. (2014) and MacKinnon and Webb (2015a) consider RI tests using tests statistics that are asymptotically symmetric. However, their inference methods do not perform well with very few treated groups. In contrast, our method provides a valid correction for heteroskedasticity even when there is only one treated group.

Finally, our paper is also related to the Behrens-Fisher problem. They considered the problem of hypothesis testing concerning the difference between the means of two normally distributed populations when the variances of the two populations are not assumed to be equal. In order to take intra-group and serial correlation into account, we consider a linear combination of the errors so that the DID estimator collapses into a simple difference between treated and control groups’ averages. While there are several solutions to this problem with good properties even in very small samples, there is, to the extent of our knowledge, no solution for the case where there is only one observation in one of the groups. Our assumption that, conditional on a set of observable variables, the distribution of the errors does not depend on treatment status guarantees that we can learn about the distribution of the treated groups based on the residuals of the control groups, while still allowing for some heteroskedasticity. Our method would work in any situation in which the estimator can be rewritten as a comparison of means. For example, this would be the case for experiments with cluster-level treatment assignment. We focus on the case of DID estimator because the scenario of very few treated groups and many control groups is more common in this case.

The remainder of this paper proceeds as follows. In Section 2 we present our base model. We briefly explain the necessary assumptions in the existing inference methods, and explain why heteroskedasticity usually invalidates inference methods designed to deal with the case of few treated groups. Then we derive an alternative inference method that corrects for heteroskedasticity even when there is only one treated group.
group. In Section 3 we extend our inference method to FGLS estimation. In Section 4 we consider an
alternative application of our method that relies on a different set of assumptions when the number of pre-
treatment periods is large. In Section 5, we extend our inference method to linear factor models with few
treated groups. In Section 6 we contrast our inference method with the RI approach. We perform Monte
Carlo simulations to examine the performance of existing inference methods and to compare that to the
performance of our method with heteroskedasticity correction in Section 7, while we compare the different
inference methods by simulating placebo laws in real datasets in Section 8. We conclude in Section 9.

2 Base Model

2.1 A Review of Existing Methods

Consider a group x time DID aggregate model:

\[ Y_{jt} = \alpha d_{jt} + \theta_j + \gamma_t + \eta_{jt} \]  

where \( Y_{jt} \) represents the outcome of group \( j \) at time \( t \); \( d_{jt} \) is the policy variable, so \( \alpha \) is the main parameter of interest; \( \theta_j \) is a time-invariant fixed effect for group \( j \), while \( \gamma_t \) is a time fixed-effect; \( \eta_{jt} \) is a group x time error term that might be correlated over time, but uncorrelated across groups. Depending on the application, “groups” might stand for states, counties, countries, and so on. We assume that \( d_{jt} \) is nonstochastic.

We start considering a group x time DID aggregate model because it is well known that this way we take
into account any possible individual-level within group x time cell correlation in the errors (DL and Moulton
(1986)). Therefore, we can focus on the inference problems that are still unsettled in the literature, which
is how to deal with serial correlation and heteroskedasticity when there are few treated groups. However,
both the diagnosis of the inference problem with existing methods and the solutions we propose are valid
whether we have aggregate or individual-level data. Note that, without individual-level covariates, the DID
estimator with individual-level data will be numerically the same as the estimator with aggregated data if
we use the number of observations per group x time cell as sampling weights.

There are \( N_1 \) treated groups and \( N_0 \) control groups. Let us assume that \( d_{jt} \) changes to 1 for all treated
groups starting after date $t^\ast$. In this case, the DID estimator will be given by:

\[
\hat{\alpha} = \frac{1}{N_1} \sum_{j=1}^{N_1} \left[ \frac{1}{T - t^\ast} \sum_{t=t^\ast+1}^{T} Y_{jt} - \frac{1}{t^\ast} \sum_{t=1}^{t^\ast} Y_{jt} \right] - \frac{1}{N_0} \sum_{j=N_1+1}^{N} \left[ \frac{1}{T - t^\ast} \sum_{t=t^\ast+1}^{T} Y_{jt} - \frac{1}{t^\ast} \sum_{t=1}^{t^\ast} Y_{jt} \right]
\]

\[
= \alpha + \frac{1}{N_1} \sum_{j=1}^{N_1} W_j - \frac{1}{N_0} \sum_{j=N_1+1}^{N} W_j
\]

(2)

where $W_j = \frac{1}{T - t^\ast} \sum_{t=t^\ast+1}^{T} \hat{\eta}_{jt} - \frac{1}{t^\ast} \sum_{t=1}^{t^\ast} \hat{\eta}_{jt}$.

It is clear from equation 2 that consistency of $\hat{\alpha}$ will depend on both $N_1 \to \infty$ and $N_0 \to \infty$. As shown in CT, if the number of treated groups ($N_1$) and the number of periods ($T$) are fixed, then the DID estimator is unbiased. However, this estimator is not consistent, since the first term, $\frac{1}{N_1} \sum_{j=1}^{N_1} W_j$, would not converge to zero when $N_0 \to \infty$.

The variance of the DID estimator, under the assumption that $\eta_{jt}$ are independent across $j$, is given by:

\[
\text{var}(\hat{\alpha}) = \left[ \frac{1}{N_1} \right]^2 \sum_{j=1}^{N_1} \text{var}(W_j) + \left[ \frac{1}{N_0} \right]^2 \sum_{j=N_1+1}^{N} \text{var}(W_j)
\]

(3)

Note that the variance of the DID estimator is the sum of two components: the variance of the treated groups pre/post comparison and the variance of the control groups pre/post comparison. We allow for any kind of correlation between $\eta_{jt}$ and $\eta_{jt'}$, which is captured in the linear combination of the errors $W_j$.

When there are many treated and control groups, Bertrand et al. (2004) suggest that CRVE at the group level works well, as this method allows for unrestricted intra-group and serial correlation in the residuals $\eta_{jt}$.

One important point is that this method is not only cluster-robust, but also heteroskedasticity-robust. The CRVE has a very intuitive formula in the DID framework:\(^{16}\)

\[
\text{var}(\hat{\alpha})_{\text{cluster}} = \left[ \frac{1}{N_1} \right]^2 \sum_{j=1}^{N_1} \hat{W}_j^2 + \left[ \frac{1}{N_0} \right]^2 \sum_{j=N_1+1}^{N} \hat{W}_j^2
\]

(4)

where $\hat{W}_j = \frac{1}{T - t^\ast} \sum_{t=t^\ast+1}^{T} \hat{\eta}_{jt} - \frac{1}{t^\ast} \sum_{t=1}^{t^\ast} \hat{\eta}_{jt}$.

With CRVE, we calculate each component of the variance of the DID estimator separately. In other words, we use the residuals of the treated groups to calculate the component related to the treated groups,

\(^{16}\)Up to a degrees-of-freedom correction.
and the residuals of the control groups to calculate the component related to the control groups. This way, CRVE allows for unrestricted heteroskedasticity. While CRVE is very appealing when there are many treated and many control groups, equation 4 makes it clear why it becomes unappealing when there are few treated groups. In the extreme case when \( N_1 = 1 \), we will have \( \hat{W}_{1j} = 0 \) by construction. Therefore, the variance of the DID estimator would be severely underestimated (MacKinnon and Webb (2015b)). The same problem applies to other clustered standard errors corrections such as BRL (Bell and McCaffrey (2002)). It is also problematic to implement heteroskedasticity-robust cluster bootstrap methods such as pairs-bootstrap and wild cluster bootstrap when there are few treated groups. In pairs-bootstrap, there is a high probability that the bootstrap sample will not include a treated unit. Wild cluster bootstrap generates variation in the residuals of each \( j \) by randomizing whether its residual will be \( \hat{\eta}_{jt} \) or \( -\hat{\eta}_{jt} \). However, in the extreme case with only one treated, the wild cluster bootstrap would not generate variation in the treated group, since \( \hat{W}_{1j} = 0 \).

Another alternative presented by Bertrand et al. (2004) is to collapse the pre- and post-information. This approach would take care of the auto-correlation problem. However, in order to allow for heteroskedasticity, one would have to use heteroskedasticity-robust standard errors. In this case, this method would also fail when there are few treated groups.

It is clear, then, that the inference problem in DID models with few treated groups revolves around how to estimate the component of the DID estimator variance related to the treated group using the residuals \( \hat{\eta}_{jt} \). Alternative methods use information on the residuals of the control groups in order to estimate the component of the variance related to the treated groups. These methods, however, rely on specific assumptions regarding the error terms. DL assume that the group x time errors are normal, homoskedastic, and serially uncorrelated. Under these assumptions, the variance of \( \hat{\alpha} \) becomes:

\[
\text{var}(\hat{\alpha}) = \frac{1}{NT} \frac{\sigma^2_\eta}{p(1-p)}
\]  

(5)

where \( \text{var}(\eta_{jt}) = \sigma^2_\eta \) and \( p \) is the proportion of treated groups. Therefore, under these assumptions, one could recover the variance of \( \hat{\alpha} \) by estimating \( \sigma^2_\eta \) using the \( T \times N \) estimated residuals \( \hat{\eta}_{jt} \). As suggested by DL, if \( T \times N \) is small, then one should compare the test statistic \( t = \hat{\alpha} / \sqrt{\text{var}(\hat{\alpha})} \) to the student-t distribution instead of calculating the critical values based on the normal distribution. The assumption that errors are serially uncorrelated, however, might be unappealing in DID applications (Bertrand et al. (2004)).

CT provide an interesting alternative inference method that allows for unrestricted auto-correlation in the error terms. Their method uses the residuals of the control groups to estimate the distribution of the
DID estimator under the null. The key difference relative to DL is that CT look at a linear combination of the residuals that takes into account any form of serial correlation instead of using the group x time level residuals. In the simpler case with only one treated group, $\hat{\alpha} - \alpha$ would converge to $W_1$ when $N_0 \to \infty$. In this case, they use $\{\hat{W}_j\}_{j=2}^{N_0+1}$ (a linear combination of the control group residuals) to construct the distribution of $W_1$. While CT relax the assumption of no auto-correlation, it requires that errors are i.i.d. across groups, so that $\{\hat{W}_j\}_{j=2}^{N_0+1}$ approximates the distribution of $W_1$ when $N_0 \to \infty$.

Finally, cluster residual bootstrap methods resample the residuals while holding the regressors constant throughout the pseudo-samples. The residuals are resampled at the group level, so that the correlation structure is preserved. It is possible that a treated group receives the residuals of a control group. While this helps when there are only few treated groups, a crucial assumption is again that errors are homoskedastic.

### 2.2 Leading Example: Variation in Group Sizes

As seen in Section 2.1, CRVE in DID models with few treated groups severely underestimates the variance of $\hat{\alpha}$. Alternative methods such as DL, CT, and cluster residual bootstrap require strong distributional assumptions on the errors. In particular, they all require some kind of homoskedasticity in the aggregate group x time model. In this section, we show that the group x time DID aggregate models will be inherently heteroskedastic when there is variation in the number of observations per group and derive the implications of this heteroskedasticity for these inference methods. However, it is important to point out that this is not the only case that might generate heteroskedasticity in the group x time aggregate DID model.

We start with a simple individual-level DID model:

$$Y_{ijt} = \alpha d_{jt} + \theta_j + \gamma_t + \nu_{jt} + \epsilon_{ijt}$$

where $Y_{ijt}$ represents the outcome of individual $i$ in group $j$ at time $t$; $\nu_{jt}$ is a group x time error term (possibly correlated over time), and $\epsilon_{ijt}$ is an individual-level error term. The main features that define a “group” in this setting are that the treatment occurs at the group level and that errors ($\nu_{jt} + \epsilon_{ijt}$) of two individuals in the same group might be correlated, while errors of individuals in different groups are uncorrelated. For ease of exposition, we assume that $\epsilon_{ijt}$ are all uncorrelated, while allowing for unrestricted auto-correlation in $\nu_{jt}$. However, our correction will require weaker assumptions on the error structure, as will be presented in Section 2.3.
When we aggregate by group x time, our model becomes the same as the one in equation 1:

\[ Y_{jt} = \alpha d_{jt} + \theta_j + \gamma_t + \eta_{jt} \]  

(7)

The important point is that errors in the group x time aggregate model (\(\eta_{jt}\)) are heteroskedastic across \(j\), unless \(M(j,t)\) is constant across \(j\). More specifically:

\[ \eta_{jt} = \nu_{jt} + \frac{1}{M(j,t)} \sum_{i=1}^{M(j,t)} \epsilon_{ijt} \]  

(8)

where \(M(j,t)\) is the number of observations in group \(t\) at time \(t\). Therefore, assuming for simplicity that \(M(j,t) = M_j\) is constant across \(j\) and \(T\) is fixed, we have that the variance of \(W_j\) conditional on \(M_j\) is given by:

\[
\text{var}(W_j|M_j) = \text{var} \left( \frac{1}{T-t^*} \sum_{t=t^*+1}^{T} \eta_{jt} - \frac{1}{t^*} \sum_{t=1}^{t^*} \eta_{jt} | M_j \right) \\
= \text{var} \left( \frac{1}{T-t^*} \sum_{t=t^*+1}^{T} \nu_{jt} - \frac{1}{t^*} \sum_{t=1}^{t^*} \nu_{jt} + \frac{1}{T-t^*} \sum_{t=t^*+1}^{T} \left[ \frac{1}{M_j} \sum_{i=1}^{M_j} \epsilon_{ijt} \right] - \frac{1}{t^*} \sum_{t=1}^{t^*} \left[ \frac{1}{M_j} \sum_{i=1}^{M_j} \epsilon_{ijt} \right] | M_j \right) \\
= A + \frac{B}{M_j} 
\]  

(9)

for constants \(A\) and \(B\), regardless of the auto-correlation of \(\nu_{jt}\).\(^\text{17}\)

We are assuming so far that we have a panel of repeated cross-sections, so that \(\epsilon_{ijt}\) are not correlated over time. If we had a panel and allow for the individual-level residuals to be auto-correlated, then we would have another term that would depend on the \(\epsilon_{ijt}\) auto-correlation parameter divided by the number of observations, so we would still end up with the same formula, \(\text{var}(W_j|M_j) = A + \frac{B}{M_j}\). This formula might also remain valid even in situations where, for example, the correlation between two observations in the same school is stronger than the correlation between two observations in the same state but in different schools.\(^\text{18}\) Finally, we do not need to assume that the individual-level model is homoskedastic to have the formula \(\text{var}(W_j|M_j) = A + \frac{B}{M_j}\).

\(^{17}\)When the number of observations per group is not constant over time, the formula will be: \(\text{var}(W_j) = \tilde{A} + \tilde{B} \left( \frac{1}{T-t^*} \right)^2 \sum_{t=t^*+1}^{T} \frac{1}{M_j} + \left( \frac{1}{t^*} \right)^2 \sum_{t=1}^{t^*} \frac{1}{M_j} \), for constants \(\tilde{A}\) and \(\tilde{B}\).

\(^{18}\)This would be the case, for example, in a model \(Y_{ikjt} = \alpha d_{jt} + \theta_j + \gamma_t + \nu_{jt} + \omega_{kjt} + \epsilon_{ijkjt}\) for student \(i\) in school \(k\), state \(j\) and time \(t\). We allow for a common school-level shock \(\omega_{kjt}\) in addition to the state-level shock \(\nu_{jt}\). If the number of schools per state grow at the same rate as the number of observations, then this model would also generate \(\text{var}(W_j|M_j) = A + \frac{B}{M_j}\).
This heteroskedasticity in the error terms of the aggregate model implies that, when the number of observations in the treated groups are (large) small relative to the number of observations in the control groups, we would (over-) underestimate the component of the variance related to the treated group when we estimate it using information from the control groups. This implies that inference methods that do not take that into account would tend to (under-) over-reject the null hypothesis when the number of observations of the treated groups is (large) small. This will be the case whether one has access to individual-level or aggregate data.

Note that, if $A > 0$, this would not be a problem when $M(j,t) \to \infty$. In this case, $\text{var}(W_j) \to A$ for all $j$. In other words, when the number of observations in each group x cell is large, then the correlated part of the error would dominate. In this case, if we assume that the group x time error $\nu_{jt}$ is i.i.d., then $\frac{\text{var}(W_j)}{\text{var}(W_j')}$ $\to$ 1, which implies that the residuals of the control groups would be a good approximation for the distribution of the treated groups error even when the number of observations in each group is different. This is one of the main rationales used in DL to justify the homoskedasticity assumption in the aggregate model.

However, an interesting case occurs when $A = 0$. In this case, even though $\text{var}(W_j) \to 0$ for all $j$ when $M_j \to \infty$, the ratios $\frac{\text{var}(W_j)}{\text{var}(W_j')}$ remain constant (unless $\frac{M_j}{M_j'} \to 1$), which implies that the aggregate model remains heteroskedastic even asymptotically. Therefore, CT, DL, and cluster residual bootstrap would tend to (under-) over-reject the null hypothesis when the number of observations of the treated groups are (large) small relative to the number of observations of the control groups even when there is a large number of individual observations. While $A \approx 0$ implies that the group x time common shock is not strong, note that this does not mean that standard inference using OLS regression on the individual-level data would be reliable. Even in the absence of group x time common shocks, OLS standard errors might be underestimated if there is important serial correlation in the individual level error, $\epsilon_{ijt}$.

### 2.3 Inference with Heteroskedasticity Correction

As discussed in Section 2.1, the main challenge in estimating the variance of $\hat{\alpha}$ when there are few treated groups is how to estimate the component related to the treated groups. The CRVE estimates this component of the variance without using information from the control groups. While this approach has the appealing property of allowing for unrestricted heteroskedasticity, it is unfeasible when the number of treated groups is small. On the other extreme, other methods surpass the problem of few treated groups by using information from the control groups. The problem with these approaches is that they require homoskedasticity.

In this section, we derive an inference method that uses information from the control groups to estimate
the variance of the treated groups while still allowing for heteroskedasticity. Intuitively, our approach assumes
that we know how the heteroskedasticity is generated, which is the case when, for example, heteroskedasticity
is generated by variation in the number of observations per group. Under this assumption, we can re-scale
the residuals of the control groups using the (estimated) structure of the heteroskedasticity in a way that
allows us to use this information to estimate the distribution of the error for the treated groups. Our method
only requires information on the heteroskedasticity structure for a linear combination of the errors, which
implies that we do not have to impose strong assumptions on the structure of the serial correlation of the
errors. While we motivate our methods based on heteroskedasticity generated by variation in the number of
groups, it is important to note that our method is more general.

More formally, we assume we have a total of \( N \) groups where the first \( N_1 \) groups are treated. For
simplicity, we consider first the case where \( d_{jt} \) changes to 1 for all treated groups starting after date \( t^* \).
Let \( X_j \) be a vector of observable covariates that do not necessarily enter in model 1 and \( d_j \) be an indicator
variable equal to 1 if group \( j \) is treated. We will define our assumptions directly on the linear combi-
nation of the errors \( W_j = \frac{1}{T-t^*} \sum_{t=t^*+1}^T \eta_{jt} - \frac{1}{t^*} \sum_{t=1}^{t^*} \eta_{jt} \). The main assumptions for our method are:

1. \( \{W_j, X_j\} \) is i.i.d. across \( j \in \{1, \ldots, N_1\} \), i.i.d. across \( j \in \{N_1 + 1, \ldots, N\} \) and independently distributed
   across \( j \in \{1, \ldots, N\} \).

2. \( W_j | X_j, d_j \stackrel{d}{=} W_j | \tilde{X}_j \), where \( \tilde{X}_j \) is a subset of \( X_j \).

3. \( W_j | \tilde{X}_j \) has the same distribution across \( \tilde{X}_j \) up to a scale parameter.

4. \( E[W_j | X_j, d_j] = E[W_j | X_j] = 0 \)

Note that assumption 1 does not require that treatment is randomly assigned. Instead, we might consider
a case where, for example, larger states are more likely to switch policies than smaller states. Assumption
2 implies that, conditional on a subset of observable covariates, the distribution of \( W_j \) will be the same
independently of the treatment status. This is crucial for our method, as it guarantees that we can extrapolate
information from the control groups residuals to estimate the distribution of the treated groups errors. This
assumption would not be required with large \( N_1 \) and \( N_0 \) for inference with heteroskedasticity-robust methods.
In this case, it would be possible to allow for different distributions conditional on treatment status since
there would be enough observations to estimate the variance component related to the treated groups using
only information from the treated groups. In our setting, this would not be feasible since we assume that
the number of treated groups is fixed and small. Assumption 3 implies that the distribution of \( W_j | X_j \)
only depends on \( X_j \) through the variance parameter. This assumption reduces the dimensionality of the problem. It might be possible to relax this assumption and estimate the conditional distribution of \( W_j|\tilde{X}_j \) non-parametrically. However, this would require very large number of control groups, \( N_0 \). Finally, condition 4 is the standard identification assumption for DID.

Our method is an extension of the cluster residual bootstrap with \( H_0 \) imposed where we correct the residuals for heteroskedasticity. In cluster residual bootstrap with \( H_0 \) imposed, we estimate the DID regression imposing that \( \alpha = 0 \), generating the residuals \( \{ \hat{W}_{j}^{R}\}_{i=1}^{N} \). If the errors are homoskedastic, then, under the null, \( \hat{W}_{j}^{R} \) would have the same distribution across \( j \), which implies that we can resample with replacement \( B \) times from \( \{ \hat{W}_{j}^{R}\}_{i=1}^{N} \), generating \( \{ \hat{W}_{j,b}^{R}\}_{i=1}^{N} \). Then we can calculate our bootstrap estimates as \( \hat{\alpha}_b = \frac{1}{N_1} \sum_{j=1}^{N_1} \hat{W}_{j,b}^{R} - \frac{1}{N_0} \sum_{j=N_1+1}^{N} \hat{W}_{j,b}^{R} \). Note that, in our setting, we do not need to work with the group \( x \) time residuals \( \hat{\eta}_{jt} \) to construct our bootstrap estimates. Instead, we can work with a linear combination of the residuals that takes into account any form of auto-correlation in the residuals. This is one of the key insights of CT.

As explained in Section 2.1, the problem with cluster residual bootstrap is that it requires the residuals to be homoskedastic. In Theorem 2 in Appendix A.1, we show that, if we know the variance of each random variable \( W_j \) conditional on \( X_j \), then we can re-scale the residuals \( \hat{W}_{j,b}^{R} \) so that it has (asymptotically) the same distribution as unit \( j \). First, we normalize each observed \( \hat{W}_{j}^{R} \) by \( \hat{W}_{j}^{norm} = \hat{W}_{j}^{R} \sqrt{\frac{1}{\text{var}(\hat{W}_{j}|X_j)}} \). Then we generate a bootstrap sample with the re-scaled residuals \( \hat{W}_{j,b} = \hat{W}_{j,b}^{norm} \sqrt{\text{var}(\hat{W}_{j}|X_j)} \). As a result, this procedure generates bootstrap estimators \( \hat{\alpha}_b = \frac{1}{N_1} \sum_{j=1}^{N_1} \hat{W}_{j,b} - \frac{1}{N_0} \sum_{j=N_1+1}^{N} \hat{W}_{j,b} \) that can be used to draw inferences about \( \alpha \) with the correct size.\(^{19}\) The main assumption we need is that \( \{W_j\}_{j=1}^{N} \), which is a linear combination of the error terms \( \eta_{jt} \), are independent across \( j \) and have the same distribution up to the variance parameter.\(^{20}\) It is important to note that we only need the variance of a linear combination of the errors. This point is crucial for our method, because we do not need to specify the serial correlation structure of the errors \( \eta_{jt} \).

The main problem, however, is that \( \text{var}(W_j|X_j) \) is generally unknown, so it needs to be estimated. In Theorem 3 in Appendix A.1, we show that this heteroskedasticity correction works asymptotically when

\(^{19}\)As we assume a setting in which the number of treated groups is fixed and small, we have to consider for inference the distribution of \( \hat{\alpha} \) conditional on \( \{X_j\}_{j=1}^{N} \). Note that CT would be valid as unconditional inference if we assume that \( \{W_j, X_j\} \) is i.i.d. across \( j \in \{1, ..., N\} \). However, CT would not provide a reasonable solution conditional on the data at hand. As we show in our example in Section 2.2, CT would provide a biased test conditional on the information about group sizes. If \( \{W_j, X_j\} \) is not identically distributed (as is allowed in assumption 1), then it would be impossible to consistently estimate \( \text{var}(W_j|d_j) = 1 \) for an unconditional test, because we would only have a finite number of treated observations (unless we have more information about the distribution of \( X_j|d_j \)). Therefore, it would not be possible to conduct unconditional inference. In Section 6, we discuss in more detail the case for conditional inference in the RI framework.

\(^{20}\)Note that this assumption is weaker than assuming that the sequences \( \{\eta_{1,t}, ..., \eta_{jt}\} \) are independent and have the same distribution up to a variance parameter across \( j \).
\[ N_0 \to \infty \text{ if we have a consistent estimator for } \text{var}(W_j|X_j). \] That is, we can use \( \text{var}(W_j|X_j) \) to generate \( \hat{W}_{j,b} \). Since we only need a consistent estimator for \( \text{var}(W_j|X_j) \), in theory, one could estimate the conditional variance function non-parametrically. In practice, however, a non-parametric estimator would likely require a large number of control groups.

In our leading example where heteroskedasticity is generated by variation in group sizes, we show in Section 2.2 that we can derive a parsimonious function for the conditional variance without having to impose a strong structure on the error terms. More specifically, in this example, the conditional variance function would be given by \( \text{var}(W_j|X_j, d_j) = \text{var}(W_j|M_j) = A + B M_j \), for constants \( A \) and \( B \), where \( X_j \) is the set of observable variables including \( M_j \). We show in Lemma 4 in Appendix A.1 that we can get a consistent estimator for \( \text{var}(W_j|M_j) \) by regressing \((\hat{W}_j^R)^2\) on \( 1/M_j \) and a constant.\(^{21}\) Note that we do not need individual-level data to apply this method, provided that we have information on the number of observations that were used to calculate the group x time averages. While we present our method for the group x time aggregate model, we show below that it is straightforward to extend our method to the case with individual-level data.

Finally, a problem with cluster bootstrap methods when there are few clusters is that there will be few possible combinations of bootstrap samples (Cameron et al. (2008), Webb (2014), and MacKinnon and Webb (2015a)). To ameliorate this problem, we apply the idea of wild cluster bootstrap to our method. Therefore, for each \( j \), we sample either \( \hat{W}_{j,b} \) with probability 0.5 or \( -\hat{W}_{j,b} \) with probability 0.5. This procedure provides a smoother bootstrap distribution. MacKinnon and Webb (2015a) recommend a similar procedure for permutation tests.

Summarizing, our bootstrap procedure, for this specific case, consists of:

1. Calculate the DID estimate:

\[
\hat{\alpha} = \frac{1}{N_1} \sum_{j=1}^{N_1} \left[ \frac{1}{T-t^*} \sum_{t=t^*+1}^{T} Y_{jt} - \frac{1}{t^*-1} \sum_{t=1}^{t^*} Y_{jt} \right] - \frac{1}{N_0} \sum_{j=N_1+1}^{N} \left[ \frac{1}{T-t^*} \sum_{t=t^*+1}^{T} Y_{jt} - \frac{1}{t^*-1} \sum_{t=1}^{t^*} Y_{jt} \right]
\]

2. Estimate the DID model with \( H_0 \) imposed \( (Y_{jt} = \alpha_0 d_{jt} + \theta_j + \gamma_t + \eta_{jt}) \), and obtain \( \{\hat{W}_{j,b}^R\}_{j=1}^{N} \). Usually the null will be \( \alpha_0 = 0 \).

3. Estimate \( \text{var}(W_j|M_j) \) by regressing \((\hat{W}_j^R)^2\) on a constant and \( 1/M_j \).

\(^{21}\)When the number of observations per group is not constant over time, we regress \((\hat{W}_j^R)^2\) on
\[
\left( \frac{1}{T-t^*} \right)^2 \sum_{t=t^*+1}^{T} \frac{1}{M(j,t)} + \left( \frac{1}{t^*-1} \right)^2 \sum_{t=1}^{t^*} \frac{1}{M(j,t)} \] and a constant.
4. Use $\text{var}(W_j|M_j)$ to obtain the normalized residuals $\hat{W}_j^\text{norm} = \hat{W}_j R \frac{1}{\text{var}(W_j|R[M_j])}$.

5. Do $B$ iterations of this step. On the $b$th iteration:

   (a) Resample with replacement $N$ times from $\left\{ \hat{W}_j^\text{norm} \right\}_{i=1}^N$ to obtain $\left\{ \tilde{W}_{j,b} \right\}_{i=1}^N$, where $\tilde{W}_{j,b} = \hat{W}_j^\text{norm} \sqrt{\text{var}(W_j|M_j)}$ with probability 0.5 and $-\hat{W}_j^\text{norm} \sqrt{\text{var}(W_j|M_j)}$ with probability 0.5.

   (b) Calculate $\hat{\alpha}_b = \frac{1}{N_1} \sum_{j=1}^{N_1} \tilde{W}_{j,b} - \frac{1}{N_0} \sum_{j=N_1+1}^{N} \tilde{W}_{j,b}$.

6. Reject $H_0$ at level $a$ if and only if $\hat{\alpha} < \hat{\alpha}_b[a/2]$ or $\hat{\alpha} > \hat{\alpha}_b[1-a/2]$, where $\hat{\alpha}_b[q]$ denotes the $q$th quantile of $\hat{\alpha}_1, ..., \hat{\alpha}_B$.

The method described above works when all the treated groups start treatment in the same period $t^*$. Consider a general case where there are $N_0$ control groups and $N_k$ treated groups that start treatment after period $t^*_k$, with $k = 1, ..., K$. We show in Appendix A.2 that, for large $N_0$, the DID estimator is a weighted average of $K$ DID estimators, each one using one $k > 0$ as treated groups and $k = 0$ as control groups. The weights are given by $\frac{N_k(T-t^*_k)}{\sum_{k=1}^{K} N_k(T-t^*_k)}$. Therefore, the weights increase with the number of treated groups that start treatment after $t^*_k$ ($N_k$) and are higher when $t^*_k$ divides the total number of periods in half. Let $\hat{W}^{R,k}_j = \frac{1}{T-t^*_k} \sum_{t=t^*_k+1}^{T} \hat{\eta}^R_{jt} - \frac{1}{t^*_k} \sum_{t=1}^{t^*_k} \hat{\eta}^R_{jt}$. We generalize our method to this case by estimating $K$ functions $\text{var}(W^k_j|M_j)$ by regressing $(\hat{W}^{R,k}_j)^2$ on a constant and $\frac{1}{N^k_j}$. Each function $\text{var}(W^k_j|M_j)$ provides the proper rescale for the residuals of the DID regression using $k$ as the treated groups. We then calculate $\hat{\alpha}_b$ as a weighted average of these $K$ DID estimators.

We also show in Appendix A.3 that our method applies to DID models with both individual- and group-level covariates. With covariates at the group x time level, we estimate the OLS DID regressions in steps 1 and 2 of the bootstrap procedure with covariates. The other steps remain the same. If we have individual-level data, then we run the individual-level OLS regression with covariates in step 2 and then aggregate the residuals of this regression at the group x time level. The other steps in the bootstrap procedure remain the same.

3 Improving Efficiency with a FGLS

One important feature of our inference method is that we do not need to specify the structure of the serial correlation. Since the linear combination $W_j$ does not depend on $\theta_j$, we circumvent the incidental parameter problem caused by the estimation of group fixed effects. However, it might be possible to improve
efficiency by exploiting the serial correlation with a FGLS-DID estimator. This strategy, however, presents some challenges. First, one needs to impose some structure on the entire variance/covariance matrix. Also, the residual $\hat{\eta}_{jt}$ depends on the group fixed effects estimator, which will not be consistent if $T$ is fixed. This complicates the estimation of the variance/covariance matrix even if parametric assumptions on the variance/covariance matrix are correct. Finally, with few treated groups, the FGLS estimator might not be normally distributed even when $N_0 \to \infty$. We show now that it is possible to combine FGLS estimation with our inference method. This will allow for robust inference in case the serial correlation is misspecified, estimators for the serial correlations parameters are biased, or errors are not normally distributed.

Since we assume that errors are uncorrelated across $j$, the variance/covariance matrix of $\eta_{jt}$ is block diagonal with $T \times T$ blocks given by $\Omega_j$. We assume that $\Omega_j = \Omega(\bar{X}_j)$ that converges to $\bar{\Omega}(\bar{X}_j)$ (we allow $\bar{\Omega}(\bar{X}_j)$ to be biased). The FGLS estimator using $\bar{\Omega}(\bar{X}_j)$ will be a linear estimator $\hat{\alpha}_{FGLS} = \sum_{t=1}^{T} \sum_{j=1}^{N} \hat{a}_{jt} Y_{jt}$. In Appendix A.4, we show that, in the case with only one treated group, $\hat{\alpha}_{FGLS} \overset{d}{\to} \sum_{t=1}^{T} \bar{a}_{1t} \eta_{1t}$, where $\bar{a}_1 = (\bar{a}_{11}, \ldots, \bar{a}_{1T})'$ is defined by:

$$\bar{a}_1 = \arg\min_{a_1} a_1' \bar{\Omega}(\bar{X}_1) a_1$$

subject to: $\sum_{t=t'+1}^{T} a_{1t} = 1$ and $\sum_{t=1}^{T} a_{1t} = 0$ (11)

Therefore, defining the linear combination $W^*_j = \sum_{t=1}^{T} \bar{a}_{1t} \eta_{jt}$, we show in Appendix A.4 that all results from Section 2.3 applies to the FGLS estimator. The only difference is that the assumptions should be based on the linear combination $W^*_j$ instead of on the linear combination $W_j$. Note that $\hat{W}^*_0 \overset{d}{\to} W^*_0$, so we would not have an incidental parameter problem by looking at the linear combination $W^*_j$.\footnote{Another difference relative to the OLS DID is that the we have to estimate $a_{jt}$. However, since we have a consistent estimator for $a_{jt}$, this does not impose any problem to apply our method.} For our leading example presented in Section 2.2, we would still have $\text{var}(W^*_j | M_j) = A + \frac{B}{M_j}$.

So far, we only assumed that $\bar{\Omega}(\bar{X}_j)$ converges to $\bar{\Omega}(\bar{X}_j)$. So our inference method would be valid even if $\bar{\Omega}(\bar{X}_j) \neq \Omega(\bar{X}_j)$. If $\eta_{jt}$ is multivariate normal and $\bar{\Omega}(\bar{X}_j) = \Omega(\bar{X}_j)$, then we show in Appendix A.4 that our test has asymptotically the same power as a t-test based on the infeasible GLS estimator, which is the uniformly most powerful (UMP) test in this case.\footnote{The main intuition of the proof is that, even under the alternative hypothesis, we have that $\hat{W}^*_j \overset{d}{\to} W^*_j$ for all $j$ in the control group when $N_0 \to \infty$ but $N_1$ is small and fixed. Since the probability of resampling a treated group goes to zero, then the bootstrap distribution will approximate the distribution of $\hat{\alpha}_{FGLS}$ under the null even when the null is false.} Therefore, by combining our method with FGLS estimation we provide a test that is asymptotically UMP if all these assumptions are satisfied. Importantly,
if the serial correlation is misspecified, the estimators of the serial correlation parameters are biased, or the error is not normally distributed, then our test would still have the correct size while a t-test based on the FGLS estimator would be biased.

A final point is how to provide a consistent estimator $\hat{\Omega}(\tilde{X}_j)$. This is not a trivial challenge since, with fixed $T$, $\hat{\eta}_{jt} \xrightarrow{d} \eta_{jt} - \frac{1}{T} \sum_{t=1}^{T} \eta_{jt'} \neq \eta_{jt}$. Therefore, we would get biased estimators if we simply use sample analogs based on DID residuals. If we assume homoskedasticity and constant AR(p) parameters, then Hansen (2007) provides a consistent estimator for $\Omega(\tilde{X}_j) = \Omega$. However, if we consider our leading example in Section 2.2 and assume that $\nu_{jt}$ and $\epsilon_{ijt}$ follow an AR(p) model, then it is not straightforward to extend Hansen’s (2007) strategy. The main challenge is that we would not have the linearity that Hansen (2007) uses to derive the bias and provide the bias correction (see Appendix A.4). Imposing more assumptions, we provide in Appendix A.4 a consistent estimator for $\hat{\Omega}(M_j)$ for the case that all serial correlation comes from the $\epsilon_{ijt}$ and $M_j$ is large. These results suggest that the possibility of deriving a consistent estimator for $\Omega(\tilde{X}_j)$ is case specific and relies on potentially strong assumptions on the structure of the serial correlation. Therefore, our inference method provides an important safeguard for FGLS estimation in DID settings when there are few treated groups. More specifically, we provide an alternative to cluster-robust inference in FGLS when it is not possible to estimate the CRVE.

4 Heteroskedasticity Correction with Large $t^*$

One of the main features of our inference method presented in Section 2.3 is that we collapse the time series structure when we consider the linear combination of the errors $W_j$, so that the inference problem becomes equivalent to a comparison of means between treated and control groups. This is why our inference method does not require any specification of the time series structure. However, in the case with only one treated group, this implies that we would have in practice only one observation for the treated group to estimate the distribution of the treated group error. This is why a crucial assumption of our method is that we know how the heteroskedasticity is generated (that is, $W_j \mid X_j, d_j \xrightarrow{d} W_j \mid \tilde{X}_j$). Under this assumption, the residuals of the control groups are informative about the distribution of the treated group errors. We can only relax this assumption if we impose some structure on the time series.

We now show that, under strict stationarity and ergodicity of the time series, we can apply Andrews’ (2003) end-of-sample instability test to a transformation of the DID model if we have a large number of pre-treatment periods and a small number of post-treatment periods. The main idea is that with large $t^*$ and
small $T - t^*$ the DID estimator would converge in distribution to a linear combination of the post-treatment errors. Therefore, under strict stationarity and ergodicity, we can use blocks of the pre-treatment periods to estimate the distribution of $\tilde{\alpha}$. This is essentially the idea of the method suggested in CT, but exploiting the time instead of the cross-section variation.

If we collapse the cross-section variation using the transformation $\tilde{Y}_t = \frac{1}{N_1} \sum_{j=1}^{N_1} Y_{jt} - \frac{1}{N_0} \sum_{j=N_1+1}^{N} Y_{jt}$, then:

$$\tilde{Y}_t = \begin{cases} \tilde{\theta} + \tilde{\eta}_t, & \text{for } t = 1, \ldots, t^* \\ \alpha + \tilde{\theta} + \tilde{\eta}_t, & \text{for } t = t^* + 1, \ldots, T \end{cases}$$

(12)

where $\tilde{\theta} = \frac{1}{N_1} \sum_{j=1}^{N_1} \theta_j - \frac{1}{N_0} \sum_{j=N_1+1}^{N} \theta_j$ and $\tilde{\eta}_t = \frac{1}{N_1} \sum_{j=1}^{N_1} \eta_{jt} - \frac{1}{N_0} \sum_{j=N_1+1}^{N} \eta_{jt}$.

Therefore, this is a particular case of Andrews’ (2003) end-of-sample instability test in a model that includes only a constant.24 We want to test whether the average of $\tilde{Y}_t$ is different after the treatment. With group-level covariates, we can estimate the OLS DID model and then construct $\tilde{Y}_t$ using $Y_{jt} - X_{jt}'\hat{\beta}$. Since $\hat{\beta}$ is consistent, this approach will work under strict stationarity and ergodicity of $\eta_{jt}$. The same approach works if we have individual-level covariates.25

This approach might be interesting because we do not need to assume the structure of the heteroskedasticity. Also, this approach works even if we have as few as one treated and one control group. However, this approach is unfeasible if there are few pre-treatment periods. Moreover, the stationarity assumption might be violated if, for example, there is variation in the number of observations per group across time. For example, if we divide the US states in the CPS by quartiles of number of observations for each year from 1979 to 2014, then 35 out of the 51 states belonged to 3 or 4 different quartiles depending on the survey year. In this scenario, our method using the function $\text{var}(W_j|M_j)$ would still provide a valid alternative, provided that we have a large number of control groups and we know how the heteroskedasticity was generated.

5 Linear Factor Model - Large $t^*$ and Large $N_0$

We now show that the inference methods we propose can be expanded to linear factor models with few treated groups. This method has been studied in the panel data setting in Bai (2009) and analyzed in

---

24Note that the DID estimator would be given by $\hat{\alpha} = \frac{1}{T-t^*} \sum_{t=t^*+1}^{T} \tilde{Y}_t - \frac{1}{T} \sum_{t=1}^{T} \tilde{Y}_t$.

25With group-level covariates, we consider a model $Y_{jt} = \alpha d_{jt} + X_{jt}'\beta + \theta_j + \gamma_t + \eta_{jt}$. With individual-level covariates, we consider a model $Y_{ijt} = \alpha d_{ijt} + X_{ijt}'\beta + \theta_j + \gamma_t + \nu_{ijt} + \epsilon_{ijt}$. In this case, we have to impose the strict stationarity and ergodicity assumptions on $\eta_{jt} = \nu_{jt} + \frac{1}{M(j,t)} \sum_{i=1}^{M(j,t)} \epsilon_{ijt}$.
detail for estimating treatment effects of regional policies as a generalization of DID in Gobillon and Magnac (2013).

Gobillon and Magnac (2013) consider a model in which the potential outcome in the absence of treatment is given by:

\[ Y_{jt}(0) = x_{jt}\beta + f_t'\lambda_j + \eta_{jt}^{LFM} \]  

(13)

where \( x_{jt} \) are covariates, \( \lambda_i \) is a \( L \times 1 \) vector of individual effects or factor loadings, and \( f_t \) is a \( L \times 1 \) vector of time effects or factors. The treatment effect is given by \( \alpha_{jt} \), so that:

\[ Y_{jt}(1) = Y_{jt}(0) + \alpha_{jt} \]  

(14)

This model allows for more flexibility relative to the usual DID model. As shown in Gobillon and Magnac (2013), we can go back to the usual DID model by setting the restrictions \( \lambda_i = (\theta_i, 1)' \) and \( f_t = (1, \gamma_t)' \). They assume that we know the number of factors in the true DGP and that the factors are sufficiently strong so that the consistency condition for factors and factor loadings is satisfied.

As suggested in Gobillon and Magnac (2013), it is possible to estimate this model in two steps. In the first step, we estimate the linear factor model in equation 13 using the sample composed of non-treated observations over the whole period and treated observations in the pre-treatment \( (t \leq t^*) \). If \( t^* \) and \( N_0 \) tend to \( \infty \), then we get consistent estimators for \( \beta, f_t \) and \( \lambda_t \). In the second step, we estimate the counterfactual term imputing the estimated \( \beta, f_t \) and \( \lambda_t \). More specifically, we have that the average treatment on the treated effect in period \( t \) is given by:

\[ E[Y_{jt}(1) - Y_{jt}(0) | \text{treated}] = E[\alpha_{jt} | \text{treated}] = E[Y_{jt} - x_{jt}\beta - \lambda_t'f_t | \text{treated}] \]  

(15)

Therefore, we can use the empirical counterpart \( \hat{\alpha}_t = \frac{1}{N_1} \sum_{j=1}^{N_1} [Y_{jt} - x_{jt}\hat{\beta} - \hat{\lambda}_t'\hat{f}_t] \) to estimate \( E[\alpha_{jt} | \text{treated}] \). If we let \( N_0 \) and \( t^* \) go to \( \infty \) while \( N_1 \) is fixed, then:

\[ \hat{\alpha}_t = \frac{1}{N_1} \sum_{j=1}^{N_1} [Y_{jt} - x_{jt}\hat{\beta} - \hat{\lambda}_t'\hat{f}_t] \rightarrow \frac{1}{N_1} \sum_{j=1}^{N_1} [Y_{jt} - x_{jt}\beta - \lambda_t'f_t] = \]

\[ = E[\alpha_{jt} | \text{treated}] + \frac{1}{N_1} \sum_{j=1}^{N_1} \eta_{jt}^{LFM} \]  

(16)
If we want to estimate the average treatment on the treated as defined in Gobillon and Magnac (2013), we just need to use $\hat{\alpha} = \frac{1}{T-t^*} \sum_{t=t^*+1}^{T} \hat{\alpha}_t$. As $N_0$ and $t^*$ go to $\infty$ while $N_1$ and $T-t^*$ are fixed, $\hat{\alpha} - \alpha$ will converge to $\frac{1}{N_1} \sum_{j=1}^{N_1} \eta_{jt}^{LFM}$. In other words, with fixed $N_1$ and fixed $T-t^*$, the error of the linear factor model estimator will be dominated by the error of the treated groups.

This result is a natural extension of CT. The key point is that common factors and factor loads are consistently estimated, so we can use the residuals from the linear factor model $\hat{\eta}_{jt}^{LFM}$ to estimate the distribution of $\eta_{jt}^{LFM}$. Since we have both $t^* \to \infty$ and $N_0 \to \infty$, we have two alternatives in this case. We can exploit the cross-section variation using the estimated residuals from the control groups, $\frac{1}{T-t^*} \sum_{t=t^*+1}^{T} \hat{\eta}_{jt}^{LFM}$ for $j > N_1$, to approximate the distribution of the errors of the treated groups, $\frac{1}{T-t^*} \sum_{t=t^*+1}^{T} \eta_{jt}^{LFM}$ for $j \leq N_1$. Under homoskedasticity across $j$, this is essentially the method presented in CT applied to linear factor models with few treated groups. If errors are heteroskedastic, then we can use our method, provided that we know how the heteroskedasticity was generated. Alternatively, we can exploit the time series variation as shown in Section 4 provided that $\eta_{jt}^{LFM}$ is strictly stationary and ergodic.

6 Randomization Inference and Permutation Tests

We assume in our model that treatment assignment is nonstochastic, while the stochastic elements in the model come from $\eta_{jt}$, $\nu_{jt}$, and $\epsilon_{ijt}$. This departs crucially from Randomization Inference (RI), which considers that the only stochastic component of the model is the treatment assignment (Fisher (1935)). In RI, one calculates the test statistic under all possible combinations of treatment assignment, and rejects the null if the observed realization in the actual experiment is extreme enough. This idea is closely related to CT. In fact, CT propose an alternative way to implement their method which is heuristically motivated by the literature on permutation tests and RI. As stated in Lehmann and Romano (2008), RI provides exact test statistics based solely on the null of no treatment effects and the fact that treatment was randomly assigned, not depending on any assumption regarding the characteristics of outcome, covariates and residuals. Young (2015) argues that many published papers in Economics that use standard inference methods in randomized experiments produce invalid testing, and proposes the use of RI methods. While we agree that RI provides a powerful inference method in randomized experiments, we believe this approach would not provide a satisfactory inference method in our setting.

First, permutation tests should take into account the treatment assignment mechanism. In standard

---

26 Note that we get an equivalent formula in the DID model if we let $N_0$ and $t^*$ go to $\infty$ while $N_1$ and $T-t^*$ are fixed.
permutation tests where one considers all possible combinations of treatment/control status, it is implicitly assumed that all units had uniform assignment probability. This random assignment assumption guarantees that the randomization distribution provides the exact distribution of the test statistic (for an unconditional test). However, this assumption might be unreasonable in many DID applications. For example, one might believe that larger states switch policies more often than smaller states. Note that the DID identification assumption can still be valid in this scenario, while the assumption of uniform assignment probability is violated. Therefore, a standard permutation test that considers all possible combinations of treatment/control status would not provide valid inference. In this scenario, permutation tests that take into account the assignment mechanism would be valid. However, the assignment mechanisms will usually be unknown to the econometrician in DID applications. Moreover, with only one or just a few treated groups there is little hope in reliably estimating the assignment mechanism from the data. Therefore, with unknown assignment mechanisms, the assumptions for the RI approach would not be satisfied, while our method would still provide valid inference.

We argue now that, even under uniform assignment probability, RI would usually provide an unsatisfactory solution to the inference problem in our setting. The key point is that, while a standard permutation test would provide a valid unconditional test (that is, before we know the information on the size of the treated groups), it would not provide a reasonable inference solution for a researcher given the data he has at hand. The case for conditional inference traces back Fisher (1934), Pitman (1938), and Cox (1958). As McCullagh (1992) argues, unconditional tests can be “inappropriate and possibly misleading for hypotheses concerning the data at hand”, while “conditional probability calculation often provides an answer to which no right-thinking person could object”. In our example described in Section 2.2, if one has information on group sizes, then we argue it would be more reasonable to consider a test conditional on this information. The reason is that once one knows that the treated groups are (large) small relative to the control groups, then one knows that a permutation test that ignores this information would (under-) over-reject the null when the null is true, even if the assignment probabilities were uniform. In this case, this test would no longer have the correct size given the data at hand. One way of incorporating this information in a permutation test would be to apply the permutation conditional on the information of group sizes. However, if there are few control groups with the same size as the treated groups, then one would not have many possible permutations. In the extreme case where there is one treated group and no control group of the same size, this conditional permutation test would generate a p-value interval of $[0, 1]$.

Canay et al. (2014) provide alternative randomization tests that can incorporate information on group
sizes. Differently from the traditional RI theory (Fisher (1935)), Canay et al. (2014) assume that the limiting distribution of a function of the data exhibits approximate symmetric under the null, and not exact symmetry as in the traditional randomization tests. In their setting, they can work with asymptotic results in nature. Their approach might be useful in our setting because, in this alternative framework, one could do a permutation test using a test statistic that does not depend asymptotically on the size of the groups.

As an application of their method, Canay et al. (2014) suggest an inference method for DID with a finite number of treated groups \(N_1\) and many control groups \(N_0\). The main idea of their method is to consider \(N_1\) DID estimators where in each one they use one of the treated groups and all control groups to construct a DID estimator for \(\alpha\) (say, \(\hat{\alpha}_j\), for \(j = 1, ..., N_1\)). With the sequence \((\hat{\alpha}_1, ..., \hat{\alpha}_{N_1})\) they construct a test statistic given by

\[
T = \frac{\bar{\hat{\alpha}} - \alpha_0}{s_{\hat{\alpha}}/\sqrt{N_1}},
\]

where \(\bar{\hat{\alpha}} = \frac{1}{N_1} \sum_{j=1}^{N_1} \hat{\alpha}_j\) and \(s_{\hat{\alpha}} = \frac{1}{N_1 - 1} \sum_{j=1}^{N_1} (\hat{\alpha}_j - \bar{\hat{\alpha}})^2\). Then they consider sign changes given by \((g_1 \hat{\alpha}_1, ..., g_{N_1} \hat{\alpha}_{N_1})\) where \(g_j \in \{-1, 1\}\) and recalculate the test statistic. Let

\[
T^{(1)} \leq T^{(2)} \leq ... \leq T^{(N_1)}
\]

be the ordered values of the test statistic considering all sign change transformation, and let \(T^{(k)}\) be the \(N_1(1 - a)^{th}\) largest value of the test statistics, where \(a\) is the significance level. The test will reject with probability 1 if \(T > T^{(k)}\) and with probability zero if \(T < T^{(k)}\). If \(T = T^{(k)}\), we would have to randomize whether we reject the null, so that asymptotically the test has the correct size. This randomization when \(T = T^{(k)}\) translates into an important drawback for their method when there are very few treated groups. For example, if \(N_1 = 2\) then there would be a 50% probability (under the null) that rejection will be decided by randomization.\(^{27}\)

While the test would still be unbiased, it would have poor power, as they point out in remark S.2.5 (Canay et al. (2014)).\(^{28}\) This happens because they rely only on variation among the treated units. Since we also exploit variation from the control groups, our method does not suffer from this problem even when we have only one treated group.

Finally, in a recent paper, MacKinnon and Webb (2015a) suggest a permutation test on a t-statistic, which is constructed using CRVE. Based on Canay et al. (2014) approach, their method works when the numbers of treated and control groups are large enough, as asymptotically the t-statistic would have the same distribution under the null for all permutations. However, their method does not work well with very few treated groups. In particular, their method collapses to CT when there is only one treated group. The reason is that CRVE would assign an estimated variance for the treated group equal to zero, so there would

\(^{27}\)In the extreme case with \(N_1 = 1\) it would not be possible to calculate their test statistic, since \(s_{\hat{\alpha}}\) would be equal to zero. If we consider other alternatives for the test statistic such as \(|\bar{\hat{\alpha}} - \alpha_0|\), then all sign transformations would generate exactly the same value for the test statistics. In this case, the test would collapse to randomly deciding whether to reject the null with probability 5%. Therefore, although the test would reject with correct size under the null, the power would also be equal to 5% for any alternative hypothesis.

\(^{28}\)Canay et al. (2014) also consider a setting with both \(N_1\) and \(N_0\) finite. This alternative would also have poor power with very few treated groups.
not be much variation in the estimated variance of the placebo estimators. The key point is that one goes back to the original problem of estimating the variance of the treated groups using CRVE with few treated groups. By contrast, our method provides a valid correction for heteroskedasticity even when there is only one treated group.

7 Monte Carlo Evidence

In this section, we provide Monte Carlo evidence of different hypothesis testing methods in DID. We assume that the underlying data generating process (DGP) is given by:

$$Y_{ijt} = \nu_{jt} + \epsilon_{ijt}$$

In our simulations, we estimate a DID model given by equation 6 where only $j = 1$ is treated and $T = 2$, and then we test the null hypothesis of $\alpha = 0$ using different hypothesis testing methods. We consider variations in the DGP along three dimensions:

1. The number of groups: $N_0 + 1 \in \{25, 50, 100, 400\}$.

2. The intra-group correlation: $\nu_{jt}$ and $\epsilon_{ijt}$ are drawn from normal random variables. We hold constant the total variance $\text{var}(\nu_{jt} + \epsilon_{ijt}) = 1$, while changing $\rho = \frac{\sigma^2_{\nu}}{\sigma^2_{\nu} + \sigma^2_{\epsilon}} \in \{.01\%, 1\%, 4\\%\}$.

3. The number of observations within group: we draw for each group $j$ the number of observations per period from a discrete uniform random variable with range $[\underline{M}, \overline{M}] \in \{[50, 200], [200, 800], [50, 950]\}$.

For each case, we simulated 100,000 estimates. We present rejection rate results for inference using robust standard errors in the individual-level OLS regression, CT, DL, and for the cluster residual bootstrap with and without our heteroskedasticity correction. We do not include in the simulations methods that allow for unrestricted heteroskedasticity. As explained in Section 2.1, these methods do not work well when there is only one treated group. We also do not include the method suggested by MacKinnon and Webb (2015a) in the simulations because their method collapses to CT when there is only one treated group.

\[29\] In the Monte Carlo simulations, we always consider the case $M(j, t) = M_j$. In the simulations with real datasets in Section 8, there is variation in $M(j, t)$ across $t$. 
7.1 Test Size

We present in Table 1 results from simulations using 400 groups (one treated and 399 controls) for different numbers of observations per group and for different values of the intra-group correlations. In panel A, we present results when the number of individual observations per group varies from 50 to 200. Column 1 shows that average rejection rates for a test with 5% significance using robust standard errors in the individual level DID regression. The rejection rate is slightly higher than 5% when the intra-group correlation $\rho = 0.01\%$ (5.4%), but increases sharply for larger values of the intra-group correlation. The rejection rate is 19% when $\rho = 1\%$ and 42% when $\rho = 4\%$. When we use DL, CT, or cluster residual bootstrap without correction, the average rejection rate is always around 5% (columns 3, 5, and 7). However, this average rejection rate hides an important variation with respect to the number of observations in the treated group ($M_1$).

In Figure 1.A, we show rejection rates for cluster residual bootstrap without correction conditional on the size of the treated group.\(^{30}\) The rejection rate is around 14% when the treated group is in the first decile of number of observations per group, while it is only 0.8% when the treated group is in the 10th decile. Note also that this distortion in rejection rates is not confined to the extremes of the distribution of group sizes. For example, the rejection rate is 3% when the treated group is in the 6th decile of number of observations per group. We summarize this variation in rejection rates by looking at the absolute difference in rejection rates for each decile of $M_1$ relative to the average rejection rate. Then we average these absolute differences across deciles. We present these results in columns 4, 6, and 8 for the methods without heteroskedasticity correction. Conditional on the number of observations of the treated group, these methods present an average variation in the rejection rates of 3.4-3.9 percentage points for a 5% significance test.

We present rejection rates by decile of the treated group for cluster residual bootstrap without correction when $\rho = 1\%$ and when $\rho = 4\%$ in Figures 1.B and 1.C, respectively. As expected, this variation in rejection rates becomes less relevant when the intra-group correlation becomes stronger. This happens because the aggregation from individual to group x time averages induces less heteroskedasticity in the residuals when a larger share of the residual is correlated within group. Still, even when $\rho = 4\%$ the difference in rejection rates by number of observations in the treated group remains relevant. The rejection rate is around 6.5% when the treated group is in the first decile of number of observations per group, while it is 4.2% when the treated group is in the 10th decile. The average absolute difference in rejection rates for DL, CT, and for the residual bootstrap without correction is around 0.7 percentage points in this scenario.

Given that inference using these methods is problematic when there is variation in the number of obser-

\(^{30}\)Results for DL and CT are similar.
vations per group, we consider our residual bootstrap method with heteroskedasticity correction derived in Section 2.3. We present rejection rates by decile of the treated group when the intra-group correlation is 0.01%, 1%, and 4% in Figures 1.D to 1.F. Average rejection rates using our method are always around 5% and, more importantly, there is no variation with respect to the number of observations in the treated group. These results are also presented in columns 9 and 10 of Table 1. The average absolute difference in rejection rates is only around 0.1-0.2 percentage points, regardless of the value of the intra-group correlation.

In panel B of Table 1, we present the simulation results when the number of observations per group increases from [50, 200] to [200, 800]. We increase the number of observations per group while holding the ratio between the number of observations in different groups constant. Note that increasing the number of observations per group worsens the over-rejection problem of inference relying on robust OLS standard errors. When we consider DL, CT, and residual bootstrap without correction, increasing the number of observations per group ameliorates the problem of (over-) under-rejecting the null when $M_1$ is (small) large relative to the number of observations in the control groups when $\rho = 1\%$ or $\rho = 4\%$. In particular, when $\rho = 4\%$ the average absolute difference in rejection rates across deciles of $M_1$ is only 0.3 percentage points. However, increasing the number of observations has no detectable effect when the intra-group correlation is 0.01%. In this case, the individual component of the residual becomes more relevant. Therefore, the ratio between the variance of $W_1$ and the variance of $W_j$ becomes less sensitive with respect to the number of observations per group. As explained in Section 2.2, in the extreme case with $\rho = 0$, heteroskedasticity would still be a problem even when $M \rightarrow \infty$.

In panel C of Table 1, we present the simulation results when the number of observations varies from 50 to 950. Therefore, the average number of observations remains constant, but we have more variation in $M$ relative to the simulations in panel B. As expected, more variation in the number of observations per group worsens the inference problem we highlight in CT, DL, and residual bootstrap without correction. On the contrary, our residual bootstrap with heteroskedasticity correction remains accurate irrespective of the variation in the number of observations per group.

As presented in Section 2.3, our method works asymptotically when $N_0 \rightarrow \infty$. This assumption is important for two reasons. First, as in any other cluster bootstrap method, a small number of groups implies a small number of possible distinct pseudo-samples. In this case, the bootstrap distribution will not be smooth even with many bootstrap replications (Cameron et al. (2008)). In order to mitigate this problem, we apply the insight of wild cluster bootstrap to our method, so that we can generate more variation in the bootstrap samples, as explained in Section 2.3. Additionally, our method requires that we estimate
\( \text{var}(W_j|M_j) \) using the group x time aggregate data so that we can apply our heteroskedasticity correction. If there are only a few groups, then our estimator of \( \text{var}(W_j|M_j) \) will be less precise. In particular, it might be the case that \( \text{var}(W_j|M_j) < 0 \) for some \( j \), which implies that we would not be able to normalize the residual of observation \( j \). When \( \text{var}(W_j|M_j) < 0 \) for some \( j \), we use the following rule: if \( \hat{A} < 0 \), then we use \( \text{var}(W_j|M_j) = \frac{1}{M_j} \), as \( \hat{A} < 0 \) would suggest that there is not not a large intra-group correlation problem. If \( \hat{B} < 0 \), then we use \( \text{var}(W_j|M_j) = 1 \), as \( \hat{B} < 0 \) would suggest that there is not much heteroskedasticity. It is important to note that asymptotically this rule would not be relevant, since \( \text{var}(W_j|M_j) > 0 \) for all \( M_j \).

We had \( \text{var}(W_j|M_j) > 0 \) for all \( j \) in more than 99.97% of our simulations with \( N = 400 \). However, when there are fewer control groups, the function \( \text{var}(W_j|M_j) \) will be estimated with less precision.

We present in Tables 2 to 4 and in Figures 2 to 4 the simulation results when the total number of groups are 100, 50, and 25. Average rejection rates are always lower than 5.3% when the total number of groups is 100 or 50, which is reasonably close to the correct size of the test. More importantly, the average absolute difference in rejection rates is always lower than 0.5 percentage points, suggesting that there is not much variation in rejection rates depending on the size of the treated group. These results are confirmed in Figures 2 and 3. When we have 25 groups, then average rejection rates are slightly higher, at around 5.5%, and we start to have more variation in rejection rates depending on the size of the treated group. As shown in Figure 4, there is some distortion in rejection rates when the treated group is in the first decile of group size. Still, our method provides reasonably accurate hypothesis testing with 25 groups. In particular, our method provides substantial improvement relative to alternative methods when the intra-group correlation is not too strong.

As a robustness check, we consider a DGP where \( \nu_{jt} \sim \chi^2(1)/\sqrt{2} \) instead of being normally distributed.\(^{31}\) Note that, in this case, it would not be true that \( W_j|M_j \) is identically distributed up to a scale parameter. The simulation results under this alternative DGP are presented in Table 5 for \( N \in \{25, 50, 100, 400\} \) and \( \rho \in \{0.01\%, 1\%, 4\%\} \). In all simulations we consider \( M_j \) uniformly distributed between 50 and 200. We consider inference using residual bootstrap with and without heteroskedasticity correction. Our simulation results suggest that our method still provides reliable inference in this setting. The simulation results are very similar to the case where \( \nu_{jt} \) is normally distributed. In particular, our method substantially improves relative to a bootstrap without correction when the intra-group correlation is not too strong. In Section 8 we provide evidence that our inference method also improves inference relative to alternative methods in simulations with real datasets, where we do not have control over the DGP.

\(^{31}\)We divide by \( \sqrt{2} \) so that \( \text{var}(\nu_{jt}) = 1 \). This makes these simulations more comparable to the case \( \nu_{jt} \sim N(0, 1) \).
7.2 Test Power

We have focused so far on Type I error. We saw in Section 7.1 that our method is efficient in providing tests that reject the null with the correct size when the null is true. We are interested now in whether our tests have power to detect effects when the null hypothesis is false. We run the same simulations as in Section 7.1, with the difference that we now add an effect of $\beta$ standard deviations for observation $\{ijt\}$ when $d_{jt} = 1$. Given that we know the DGP in our Monte Carlo simulations, we can calculate the variance of $\hat{\alpha}$ given the parameters of the model and generate a t-statistic $t = \frac{\hat{\alpha}}{\hat{\sigma}_\alpha}$. Note that with two periods and one treated group, with $N_0 \to \infty$, the DID OLS estimator is asymptotically equivalent to the GLS estimator where the full structure of the variance/covariance matrix is known. Therefore, since the errors in our DGP are normally distributed, we also know that a test based on this t-statistic is the uniformly most powerful test (UMP) for this particular case. Given our results from Section 3, we know that our inference method has asymptotically the same power of the UMP test.

In Figure 5, we present power results for different intra-group correlation parameters and for different distributions of group sizes when there are 400 groups (1 treated and 399 control groups) separately when the treated group is above and below the median of number of observations per group. The most important feature in these graphs is that, for this particular DGP, the power of our method converges to the power of the UMP test when we have many control groups in all intra-group correlation and group size scenarios. It is also interesting to note that the power is higher when the treated group is larger. This is reasonable, since the main component of the variance of the DID estimator with few treated and many control groups comes from the variance of the treated groups. The difference in power for above- and below-median treated groups vanishes when the intra-group correlation increases. This happens because a higher intra-group correlation makes the model less heteroskedastic, so the size of the treated group would be less related to the precision of the estimator. Finally, the power of the test decreases with the intra-group correlation which reflects that, for a given number of observations per group, a higher intra-group correlation implies more volatility in the group x time regression.

When we have 25 groups (1 treated and 24 control), then the power of our method is slightly lower than the power of the UMP test (Figure 6). This is partially explained by fact that we need to estimate the function $\text{var}(W_j|M_j)$ and, with a finite number of control groups, this function would not be precisely estimated. Still, the power of our method is relatively close to the power of the UMP test, especially when the intra-group correlation is not high.
8 Simulations with Real Datasets

The results presented in Section 7 suggest that heteroskedasticity generated by variation in group sizes invalidates inference methods that rely on homoskedasticity such as DL, CT, and cluster residual bootstrap, while our method performs well in correcting for heteroskedasticity when there are 25 or more groups. However, a natural question that arises is whether these results are “externally valid.” In particular, we want to know (i) whether heteroskedasticity generated by variation in group sizes is a problem in real datasets with large number of observations, and (ii) whether our method works in real datasets, where we do not have control over the DGP. More specifically, our DGP in Section 7 implies that the real variance of $W_j$ would have exactly the relationship $\text{var}(W_j|M_j) = A + \frac{B}{M_j}$, which might not be the case in real datasets.

To illustrate the magnitude of the heteroskedasticity problem and to test the accuracy of our method, we conduct simulations of placebo interventions using two different real datasets: the American Community Survey (ACS) and the Current Population Survey (CPS).\textsuperscript{32}

We consider two different group levels for the ACS based on the geographical location of residence: Public Use Microdata Areas (PUMA) and states. Simulations using placebo interventions at the PUMA level would be a good approximation to our assumption that $N_1$ is small while $N_0 \to \infty$. Simulations using placebo interventions at the state level would mimic situations of DID designs that are commonly used in applied work where the treatment unit is a state, with a dataset that includes a very large number of observations per group x time cell. We also consider the CPS for simulations with more than two periods. As shown in Bertrand et al. (2004), this dataset exhibits an important serial correlation in the residuals, so we want to check whether our method method is efficient in correcting for that.

We use the ACS dataset for the years 2005 to 2013, and the CPS Merged Outgoing Rotation Groups for the years 1979 to 2014. We extract information on employment status and earnings for women between ages 25 and 50, following Bertrand et al. (2004). We present in Table 6 the distribution of number of observations per group x cell for the PUMA-level ACS (column 1), for the state-level ACS (column 2) and for the state-level CPS (column 3). There are, on average, 778 observations in each PUMA x time cell in the ACS. This number, however, hides an important heterogeneity in cell sizes. The 10th percentile of PUMA x time cell sizes is 174, while the 90th percentile is 1,418. There is also substantial heterogeneity in state x time cell sizes in the ACS. While the average cell size is 10,138, the 10th percentile is 1,250, while the 90th percentile is 21,099. Finally, the state x time cells in the CPS have substantially fewer observations compared to the

\textsuperscript{32}We created our ACS extract using IPUMS (Ruggles et al. (2015)).
ACS. While the average cell size is 771, the 10th percentile is 392, and the 90th percentile is 1709.

For the ACS simulations, we consider pairs of two consecutive years and estimate placebo DID regressions using one of the groups (PUMA or state) at a time as the treated group. Note that this differs from Bertrand et al. (2004) simulations, as they randomly selected half of the states to be treated. In each simulation, we test the null hypothesis that the “intervention” has no effect ($\alpha = 0$) using robust standard errors, and bootstrap with and without our heteroskedasticity correction. Since we are looking at placebo interventions, if the inference method is correct, then we would expect to reject the null roughly 5% of the time for a test with 5% significance level. For each pair of years, the number of PUMAs that appear in both years ranges from 427 to 982, leading to 5,188 regressions in total. For the state-level simulations, we have $51 \times 8 = 408$ regressions (we include Washington, D.C.). For the CPS simulations, we used 2, 4, 6, or 8 consecutive years, always using the first half of the years as pre-treatment and the second half as post-treatment. This leads to 1479 to 1785 regressions, depending on the number of years used in each regression.

### 8.1 American Community Survey (ACS) Results

In Panel A of Table 7, we present results from simulations using the PUMA-level treatments using the ACS. In column 1, we show rejection rates using OLS robust standard errors in the individual-level DID regression. Rejection rates for a 5% significance test are 7.2% when the outcome variable is employment, and 8.1% when it is log wages. This over-rejection suggests that there is important intra-group correlation that the robust individual-level standard error does not take into account. In column 3 of Table 7, we present results for the bootstrap without the heteroskedasticity correction (results for DL and CT are similar). As in the Monte Carlo simulations, average rejection rates without correction are very close to 5%. However, there is substantial variation when we look at rejection rates conditional on the size of the treated group. We present in column 4 of Table 7 the difference in rejection rates when the number of observations in the treated group is above and below the median.\(^{33}\) For both outcome variables, the rejection rate is 8 percentage points lower when the treated group has a group size above the median. This implies a rejection rate of almost 9% when the treated group is below the median, and slightly lower than 1% when the treated group is above the median. In columns 5 and 6 of Table 7, we present the rejection rates using bootstrap with our heteroskedasticity correction. For both outcomes, average rejection rate has the correct size of 5% and, more importantly, there is virtually no difference between rejection rates when the treated group is above the median.\(^{33}\)

\(^{33}\)Given that we have a limited number of simulations, we do not calculate the average absolute difference in rejection rates across deciles, as we do in the Monte Carlo simulations. For the PUMA-level simulations, there are only approximately 500 simulations for each decile. For the state-level simulations there would be only around 40 simulations for each decile.
above or below the median. Therefore, our method was successful in correcting for the heteroskedasticity problem even in a setting where we do not have control over the DGP.

We present in Panel B of Table 7 the results for state-level simulations. The most striking result in this table is that rejection rates using bootstrap without correction still depend on the size of the treated group. This happens in a dataset with, on average, more than 10,000 observations per group \( \times \) time cell. In particular, the rejection rate in the simulations with log wages as the outcome variable is zero when the treated group is below the median, and 10% when the treated group is above the median. We present rejection rates using bootstrap with our heteroskedasticity correction in columns 5 and 6. Average rejection rates are around 5%, and we cannot reject that there is no difference in rejection rates above and below the median. However, this test of our method is under-powered, since we estimate rejection rates in the state-level models based on only 408 simulations. In order to provide more precision to estimate the rejection rates of our method, we simulate DID placebo regressions randomly selecting 50 PUMAs in each simulation, which generates many more placebo estimates. These results are presented in panel C of Table ACS. We also present results DID placebo regressions randomly selecting 25 PUMAs in each simulation in Panel D of Table 7. Remarkably, our method still provides hypothesis testing with correct size regardless of the size of the treated group when \( N = 50 \) and when \( N = 25 \).

8.2 Current Population Survey (CPS) Results

We present the simulation results using the CPS in Table 8. Panel A presents rejection rates of DID models using 2 years of data, while Panels B, C, and D present rejection rates using respectively 4, 6, and 8 years. Inference with OLS robust standard errors on the individual-level model becomes worse when we include more years of data in the model (column 1). This result is consistent with the findings in Bertrand et al. (2004). The key point is that the panel structure of the CPS Merged Outgoing Rotation Groups generates serial correlation in the errors. We present rejection rates for the residual bootstrap without correction in columns 3 and 4. The average rejection rates are close to 5% irrespective of the number of periods, which was expected given that this method takes serial correlation into account by looking at a linear combination of the residuals (as in CT). However, since this linear combination of the residuals is heteroskedastic, rejection rates based on this method vary with the size of the treated group. We present rejection rates using bootstrap with our heteroskedasticity correction in columns 5 and 6. As in the ACS simulations, we cannot reject that rejection rates have the correct size on average and that rejection rates do not depend on the size of the treated group in all simulations. Therefore, our method is efficient in correcting for heteroskedasticity in a
scenario that serial correlation is important without the need to specify the structure of the serial correlation.

8.3 Power with Real Data Simulations

We saw in Sections 8.1 and 8.2 that our method provides tests with correct size in simulations with the ACS and the CPS. We now present power results from simulations with these datasets in Figure 7. Figure 7.A shows power results using the ACS with state-level treatment. When the treated group is above the median, our method is able to detect an effect size of 0.06 log points with probability greater than 70%. When the treated group is below the median, we are only able to attain this power for effects greater than 0.1 log points. This again reflects that the variance of $\hat{\alpha}$ is higher when the treated group is smaller. Figures 7.B to 7.E present results for simulations using the CPS with different numbers of time periods. The power in the CPS simulations is considerably lower than in the ACS simulations. The power to reject an effect of 0.06 log points when the treated group is above the median ranges from 26% to 41%, depending on the number of periods used in the simulations. This happens because the ACS has a much larger number of observations than the CPS. Even though we have only one treated group in all simulations, the larger number of observations in the ACS implies that the group x time variance of the error would be smaller.\textsuperscript{34}

As opposed to the power results presented in Section 7.2, we do not know the true variance of $\hat{\alpha}$, so it is not possible to compare the power of our method with the power of the UMP test. Still, results from the Monte Carlo simulations suggest that the power of our method should be very close to the power of a UMP test.

9 Conclusion

This paper shows that usual inference methods used in DID models might not perform well in the presence of heteroskedasticity when the number of treated groups is small. Then we derive an alternative inference method that corrects for heteroskedasticity when there are few treated groups (or even just one) and many control groups. With few pre-treatment periods, the main assumption is that we can model the heteroskedasticity of a linear combination of the errors. By focusing on this linear combination, we circumvent the incidental parameter problem and avoid imposing strong assumptions on the serial correlation. We focus

\textsuperscript{34}For some CPS simulations, the power when the treated group is below the median crosses the power when the treated group is above the median when the effect size is large. This happens because a large effect size would imply that $\hat{W}_j^2$ (which is calculated from a model with $H_0$ imposed) would be large, which would bias our estimate of $\text{var}(\hat{W}_j | M_j)$. Note that this does not invalidate the method, since $\text{var}(\hat{W}_j | M_j)$ is consistent under the null. Also, this distortion only appears when the power of the test was already above 90%.
on the example of variation in group sizes, in which it is possible to derive a parsimonious function for the conditional variance as a function of the number of observations per group under very mild assumptions on the errors. However, our model is more general and can be applied in any situation in which we are able to assume a structure on the variance of a linear combination of the errors, $W_j$. It is important to note that there is no heteroskedasticity-robust inference method in DID when there is only one treated group. Therefore, although our method is not robust to any form of unknown heteroskedasticity, it provides an important improvement relative to existing methods that rely on homoskedasticity. Our method can also be combined with FGLS estimation, providing a safeguard in situations where a $t$-test based on the FGLS estimator would be invalid. With many pre-treatment periods, we provide an alternative inference method that relies on strict stationarity and ergodicity of the time series instead of the assumption on how the heteroskedasticity was generated. Finally, we extend our inference method to linear factor models with few treated groups, an estimation method that has been recently proposed as an alternative to DID when there are many pre-treatment periods and many control groups.

Note: This table presents results from Monte Carlo simulations with 400 groups, as explained in Section 7. In all simulations, only one group is treated. Each line presents simulation for different values of intra-group correlation, while each panel presents results for different numbers of observations per group. We consider 5 inference methods: hypothesis testing using robust standard errors from the individual level regression, DL, CT, cluster residual bootstrap without correction, and cluster residual bootstrap with our heteroskedasticity correction. For the bootstrap methods, we imposed \( H_0 \), and we used the wild bootstrap idea of randomizing whether we multiply the residuals by 1 or -1. For each inference method, we report the average rejection rate for a 5% significance level test. We also report a measure of how rejection rates depend on the number of observations in the treated group, which we call “absolute difference”. To construct this measure, we calculate the absolute difference in rejection rates for each decile of \( M_1 \) relative to the average rejection rate, and then we average these absolute differences across deciles. We run 100,000 simulations for each \( M \times \rho \times N_0 \) scenario. The standard error for the average rejection rates is around 0.07 percentage points, while the standard error for the absolute difference is around 0.04-0.07 percentage points.

</table>

Note: This table presents results from Monte Carlo simulations with 25 groups, as explained in Section 7. In all simulations, only one group is treated. Each line presents simulation for different values of intra-group correlation, while each panel presents results for different numbers of observations per group. We consider 5 inference methods: hypothesis testing using robust standard errors from the individual level regression, DL, CT, cluster residual bootstrap without correction, and cluster residual bootstrap with our heteroskedasticity correction. For the bootstrap methods, we imposed $H_0$, and we used the wild bootstrap idea of randomizing whether we multiply the residuals by 1 or -1. For each inference method, we report the average rejection rate for a 5% significance level test. We also report a measure of how rejection rates depend on the number of observations in the treated group, which we call “absolute difference”. To construct this measure, we calculate the absolute difference in rejection rates for each decile of $M_1$ relative to the average rejection rate, and then we average these absolute differences across deciles. We run 100,000 simulations for each $M \times \rho \times N_0$ scenario. The standard error for the average rejection rates is around 0.07 percentage points, while the standard error for the absolute difference is around 0.04-0.07 percentage points.

</table>

Note: This table presents rejection rates for the simulations using ACS data. For each pair of consecutive years, we run a DID regression using one group as treated and the other groups as a control. The outcome variable is employment status or log(wages) for women aged between 25 and 40. Then we test the hypothesis that the effect of the “intervention” is equal to zero using different inference methods: hypothesis testing using robust standard errors from individual level DID model, bootstrap without and bootstrap with our heteroskedasticity correction. Panel A reports results when groups are defined as PUMAs, while Panel B reports results when groups are defined as states. In Panels C and D we present results with PUMA-level treatments using 50 and 25 randomly selected PUMAs (for each PUMA x year we simulated with 5 different randomly chosen sets of control PUMAs, leading to 25,940 simulations). We report average rejection rate and the difference in rejection rates when the size of the treated group is above or below the median. Given that we have a limited number of simulations, we do not calculate the average absolute difference in rejection rates across deciles, as we do in the Monte Carlo simulations. We present in brackets standard errors for the rejection rates. Standard errors are clustered at the treated group level. For average rejection rates (columns 1, 3, and 5), * means that we reject at 10% that the average rejection rate is equal to 5%, while for the differences in rejection rates (columns 2, 4, and 6) * means that we reject at 10% that rejection rate for $M_1$ above and below the median are equal. ** means that we reject at 5%, while *** means that we reject at 1%.

Note: This table presents rejection rates for the simulations using CPS data. In each simulation, we run a DID regression using one group as treated and the other groups as a control. The outcome variable is employment status or log(wages) for women aged between 25 and 40. Then we test the hypothesis that the effect of the “intervention” is equal to zero using different inference methods: hypothesis testing using robust standard errors from individual level DID model, bootstrap without and bootstrap with our heteroskedasticity correction. Panel A reports results of DID models using 2 consecutive years of data, while Panels B and C report results of DID models using respectively 4 and 6 consecutive years of data. We report average rejection rate and the difference in rejection rates when the size of the treated group is above or below the median. Given that we have a limited number of simulations, we do not calculate the average absolute difference in rejection rates across deciles, as we do in the Monte Carlo simulations. We present in brackets standard errors for the rejection rates. Standard errors are clustered at the treated group level. For average rejection rates (columns 1, 3, and 5), * means that we reject at 10% that the average rejection rate is equal to 5%, while for the differences in rejection rates (columns 2, 4, and 6) * means that we reject at 10% that rejection rate for $M_1$ above and below the median are equal. ** means that we reject at 5%, while *** means that we reject at 1%.
A Supplemental Appendix: Inference in Differences-in-Differences with Different Group Sizes

A.1 Proof of the Main Results

This supplemental appendix contains the main theorems and proofs of the paper “Inference in Differences-in-Differences with Different Group Sizes”. We use the same notation as in the main paper.

The aggregated model is:

\[ Y_{jt} = \alpha d_{jt} + \theta_j + \beta X_{jt} + \gamma_t + \eta_{jt} \] (18)

where \( X_{jt} \) is a \( k \times 1 \) vector of covariates. For simplicity, we start with the case that \( \beta = 0 \) and then extend to the case with covariates.

We assume \( T \) periods of time \( (t = 1, \ldots, T) \) and \( N_1 \) treated groups and \( N_0 \) control groups in such a way that \( N_0 + N_1 = N \).

Consider the restricted model in which we impose the null hypothesis, \( H_0 : \alpha = \alpha_0 \),

\[ Y_{jt} = \alpha_0 d_{jt} + \theta_j + \gamma_t + \eta_{jt} \]

We will work with a linear combination of the residuals of this regression,

\[ \tilde{W}_{j}^{R} = \frac{1}{T-t^*} \sum_{t=t^*+1}^{T} \hat{\gamma}_{jt} - \frac{1}{T} \sum_{t=1}^{T} \hat{\gamma}_{jt} \]

We can calculate the DID coefficient \( \hat{\alpha} \) based on a linear combination of \( \tilde{W}_{j}^{R} \). Define the operator \( \triangledown Y_j = \frac{1}{T-t^*} \sum_{t=t^*+1}^{T} Y_{jt} - \frac{1}{T} \sum_{t=1}^{T} Y_{jt} \). We can write \( \hat{\alpha} \) as:

\[ \hat{\alpha} - \alpha_0 = \frac{1}{N_1} \sum_{j=1}^{N_1} \tilde{W}_{j}^{R} - \frac{1}{N_0} \sum_{j=N_1+1}^{N} \tilde{W}_{j}^{R} \]

We define \( W_j \) as a linear combination of the error terms,

\[ W_j = \frac{1}{T-t^*} \sum_{t=t^*+1}^{T} \eta_{jt} - \frac{1}{T} \sum_{t=1}^{T} \eta_{jt} \]

We impose assumptions about the behavior of \( W_j \). We assume that \( T \) is fixed. In the leading example of the paper, we assume that the heteroskedasticity is generated by variation of the groups’ sample size. In this appendix, we deal with the general case, and then specialize to this example.

**Assumption 1 (Independence):** \( \{W_j, X_j\} \) is i.i.d. across \( j \in \{1, \ldots, N_1\} \), i.i.d. across \( j \in \{N_1 + 1, \ldots, N\} \) and independently distributed across \( j \in \{1, \ldots, N\} \).

**Assumption 2 (Distribution):** \( W_j | X_j, d_j \overset{d}{=} W_j | \tilde{X}_j \), where \( \tilde{X}_j \) is a subset of \( X_j \).
**Theorem 2** Define \( d_{1-rac{\alpha}{2}} \) and \( d_{\frac{\alpha}{2}} \) as the \((1 - \frac{\alpha}{2})\)th and \(\frac{\alpha}{2}\)th quantile of the empirical distribution of \((\hat{\alpha}_b - \alpha_0)\) given \(X\), for \(b = 1, \ldots, B\). Assuming that we know the variance of \(W_j | \tilde{X}_j\), under assumptions 1, 2, 3 and 4 \( P \left[ d_{1-rac{\alpha}{2}} \leq \hat{\alpha} - \alpha_0 \leq d_{\frac{\alpha}{2}} \right| \alpha_0, X \right] \rightarrow_p 1 - \alpha. 

**Proof.** We divide this proof in two parts. Define \( \Gamma\left( w \right) \equiv P \left[ \sum_{j=1}^{N_1} W_j < w | \tilde{X}_j \right] \) and \( \Gamma_b\left( w \right) \equiv P \left[ \sum_{j=1}^{N_1} W_{j,b} < w | \tilde{X}_j, b \right] \). First we show that \( \Gamma_b\left( w \right) \) converges in probability to \( \Gamma\left( w \right) \) uniformly on any compact subset of the support of \(W\), as \(N_0 \to \infty\) and \(B \to \infty\). Then, we show that \( P \left[ d_{1-rac{\alpha}{2}} \leq \hat{\alpha} - \alpha_0 \leq d_{\frac{\alpha}{2}} \right| \alpha_0, X \right] \rightarrow_p 1 - \alpha. 

Under our assumptions, \(W_j | \tilde{X}_j\)'s are independent across \(j\) and have the same distribution except by the variance, we can
write
\[
\Gamma(w) = \Pr \left[ \sum_{j=1}^{N_1} W_j < w | \tilde{X}_j \right]
= \int \ldots \int \left\{ \sum_{j=1}^{N_1} W_j < w \right\} dF_{1|\tilde{X}_1}(W_1) \cdot dF_{2|\tilde{X}_2}(W_2) \cdot \ldots \cdot dF_{N_1|\tilde{X}_{N_1}}(W_{N_1})
\]
and
\[
\tilde{F}_b(w) = \Pr \left[ \sum_{j=1}^{N_1} \tilde{W}_{j,b} < w_{j,b} | \tilde{X}_j \right]
= \int \ldots \int \left\{ \sum_{j=1}^{N_1} W_j < w \right\} d\tilde{F}_{1|\tilde{X}_1}(W_1) \cdot d\tilde{F}_{2|\tilde{X}_2}(W_2) \cdot \ldots \cdot d\tilde{F}_{N_1|\tilde{X}_{N_1}}(W_{N_1})
\]

In order to estimate this distribution, we use \( \tilde{F}_{j|\tilde{X}_j}(\cdot) \) which is the empirical CDF obtained using the re-scaled residuals \( \tilde{W}_{j,b} = \tilde{W}_{j,b} \cdot \sqrt{\frac{\text{Var}[W_j|X_j]}{\text{Var}[W_{j,b}|X_{j,b}]}}, \)

\[
\tilde{F}_{j|\tilde{X}_j}(w_j) = \frac{1}{B} \sum_{b=1}^{B} 1\{\tilde{W}_{j,b} < w_{j,b}\}
= \frac{1}{B} \sum_{b=1}^{B} \left\{ \tilde{W}_{j,b} \cdot \sqrt{\frac{\text{Var}[W_j|X_j]}{\text{Var}[W_{j,b}|X_{j,b}]} < w_j \cdot \sqrt{\frac{\text{Var}[W_j|X_j]}{\text{Var}[W_{j,b}|X_{j,b}]}} \right\}
\]

where \( w_{j,b} = w_j \cdot c_{j,b} \), with \( c_{j,b} = \sqrt{\frac{\text{Var}[W_j|X_j]}{\text{Var}[W_{j,b}|X_{j,b}]}}. \) In this case, \( c_{j,b} \) is a constant.

Define \( \tilde{F}_{j|\tilde{X}_j}^*(w_j) = \frac{1}{B} \sum_{b=1}^{B} 1\{W'_{j,b} < w_{j,b}\} \), where \( W'_{j,b} = W_{j,b} \cdot c_{j,b}. \) Note that

\[
\sup_{w_j \in \Theta} \left| \tilde{F}_{j|\tilde{X}_j}(w_j) - F_{j|\tilde{X}_j}(w_j) \right| = \sup_{w_j \in \Theta} \left| \tilde{F}_{j|\tilde{X}_j}(w_j) - \tilde{F}_{j|\tilde{X}_j}^*(w_j) + \tilde{F}_{j|\tilde{X}_j}(w_j) - F_{j|\tilde{X}_j}(w_j) \right|
\leq \sup_{w_j \in \Theta} \left| \tilde{F}_{j|\tilde{X}_j}(w_j) - \tilde{F}_{j|\tilde{X}_j}^*(w_j) \right| + \sup_{w_j \in \Theta} \left| \tilde{F}_{j|\tilde{X}_j}(w_j) - F_{j|\tilde{X}_j}(w_j) \right|
\]

\[
\sup_{w_j \in \Theta} \left| \tilde{F}_{j|\tilde{X}_j}(w_j) - \tilde{F}_{j|\tilde{X}_j}^*(w_j) \right| = \sup_{w_j \in \Theta} \left| \frac{1}{B} \sum_{b=1}^{B} \left( 1\{\tilde{W}_{j,b} < w_{j,b}\} - 1\{W'_{j,b} < w_{j,b}\} \right) \right|
\leq \frac{1}{B} \sum_{b=1}^{B} \sup_{w_j \in \Theta} \left| 1\{\tilde{W}_{j,b} < w_{j,b}\} - 1\{W'_{j,b} < w_{j,b}\} \right|
= o_p(1)
\]

In the last equality, we use the result of lemma 1, \( \tilde{W}_{j,b}^R \) converges in distribution to \( W_j. \)

Now, we work with the second term.

\[
\sup_{w_j \in \Theta} \left| \tilde{F}_{j|\tilde{X}_j}^*(w_j) - F_{j|\tilde{X}_j}(w_j) \right| \leq \sup_{w_j \in \Theta} \left| \tilde{F}_{j|\tilde{X}_j}(w_j) - \tilde{F}_{j|\tilde{X}_j}(w_j) \right| + \sup_{w_j \in \Theta} \left| \tilde{F}_{j|\tilde{X}_j}(w_j) - F_{j|\tilde{X}_j}(w_j) \right|
\]

51
Theorem 3

proposed above.

Now, we do not know the variance of $F_j | X_j(w_j)$ if we have a consistent estimator of $W_j | X_j$. Using the results above, we can show that

By assumptions 2-4,

By the results above,

Now, we show that $Pr\left[ d'_{1-\frac{\alpha}{2}} \leq \hat{\alpha} - \alpha_0 \leq d_2^{*} \mid \alpha_0, X \right] \to_p 1 - \alpha$. As $N_0 \to \infty,$

Using the results above, we can show that

The approach proposed to estimate $\tilde{W}_{j,b}$ is unfeasible since we do not know the variances of $W_j$'s. Theorem 3 shows that if we have a consistent estimator of $\sqrt{\frac{\text{Var}[W_j | X_j]}{\text{Var}[W_{j,b} | X_j,b]}}$, we can construct $\tilde{W}_{j,b} = \tilde{W}_j \cdot \sqrt{\frac{\text{Var}[W_j | X_j]}{\text{Var}[W_{j,b} | X_j,b]}}$, and use the approach proposed above.

**Theorem 3** Define $d'_{1-\frac{\alpha}{2}}$ and $d_2^{*}$ as the $(1 - \frac{\alpha}{2})$th and $\frac{\alpha}{2}$th quantile of the empirical distribution of $(\hat{\alpha}_b - \alpha_0)$ given $X$, for $b = 1, \ldots, B$. If for each $j \sqrt{\frac{\text{Var}[W_j | X_j]}{\text{Var}[W_{j,b} | X_j,b]}}$ is a consistent estimator for $\sqrt{\frac{\text{Var}[W_j | X_j]}{\text{Var}[W_{j,b} | X_j,b]}}$, under assumptions 1, 2, 3 and 4

$$Pr\left[ d'_{1-\frac{\alpha}{2}} \leq \hat{\alpha} - \alpha_0 \leq d_2^{*} \mid \alpha_0, X \right] \to_p 1 - \alpha$$

**Proof.** Now, we do not know the variance of $W_j$. In this case, we define $\hat{F}_j | X_j(\tilde{\alpha}_j) = \frac{1}{B} \sum_{b=1}^{B} 1\left\{ \tilde{W}_{j,b} < \tilde{\alpha}_j \right\}$

$$\sup_{w_j \in \Theta} \left| \hat{F}_j | X_j(\tilde{\alpha}_j) - F_j | X_j(w_j) \right| = \sup_{w_j \in \Theta} \left| \hat{F}_j | X_j(\tilde{\alpha}_j) - \tilde{F}_j | X_j(w_j) + \tilde{F}_j | X_j(w_j) - F_j | X_j(w_j) + F_j | X_j(w_j) - F_j | X_j(w_j) \right|$$

We show the previous that $\sup_{w_j \in \Theta} \left| \hat{F}_j | X_j(\tilde{\alpha}_j) - F_j | X_j(w_j) \right| = o_p(1)$ and $\sup_{w_j \in \Theta} \left| \hat{F}_j | X_j(w_j) - F_j | X_j(w_j) \right| = o_p(1)$

52
So we can write
\[ \sup_{w_j \in \Theta} \left| \hat{F}_{j|X_j} (\hat{\epsilon}_j) - \hat{F}_{j|X_j} (w_j) \right| = \sup_{w_j \in \Theta} \left| \frac{1}{B} \sum_{b=1}^{B} 1\{W'_{j,b} < w_j \cdot \hat{\epsilon}_{jb} \} - \frac{1}{B} \sum_{b=1}^{B} 1\{W'_{j,b} < w_j \cdot c_{jh} \} \right| \]
\[ \leq \frac{1}{B} \sum_{b=1}^{B} \sup_{w_j \in \Theta} \left| 1\{W'_{j,b} < w_j \cdot \hat{\epsilon}_{jb} \} - 1\{W'_{j,b} < w_j \cdot c_{jh} \} \right| \]
\[ \xrightarrow{p} 0 \text{ since } \hat{\epsilon}_{jb} \sim c_{jh}. \]

Lemma 4 shows that \( \hat{\epsilon}_{jb} \) is a consistent estimator for \( c_{jh} \).

For the leading example in the paper, the conditional variance of \( W_j \) on \( X_j \) only depends on \( M(j,t) \) and it is given by:
\[ \text{Var} [W_j | M_{j1}, ..., M_{jT}] = A + \hat{B} \left( \frac{1}{T - t^*} \sum_{t=t^*+1}^{T} \frac{1}{M(j,t)} + \frac{1}{t^*} \sum_{t=1}^{t^*} \frac{1}{M(j,t)} \right) \]
\[ = A + \hat{B} \cdot h(M(j,t)) \]
where \( A \) and \( \hat{B} \) are constants, and \( h(M(j,t)) \equiv \frac{1}{T - t^*} \sum_{t=t^*+1}^{T} \frac{1}{M(j,t)} + \frac{1}{t^*} \sum_{t=1}^{t^*} \frac{1}{M(j,t)} \). For simplicity, we work with the case in which \( M(j,t) = M_j \). In this case, the variance simplifies to \( \text{Var} [W_j | M_j] = A + \frac{\hat{B}}{M_j} \) for a constant \( B \). We assume that the distribution of \( M_j \) does not vary with \( N_0 \).

We propose a consistent estimator of \( \sqrt{\frac{\text{Var}[W_j|M_j]}{\text{Var}[W_{j_b}|M_{j_b}]}} \) based on an ordinary least squares estimator. We estimate a linear regression that relates \( \left( \hat{W}'_j \right)^2 \) with \( \frac{1}{M_j} \) and constant. We obtain \( \hat{A} \) as the least squares coefficient associated with the constant, and \( \hat{B} \) as the coefficient associated with \( \frac{1}{M_j} \), and then we use \( A \) and \( B \) to construct a consistent estimator for the \( \text{Var}[W_{j}^R|M_j] \).

\[ \text{Var} [W_{j}^R | M_j] = \hat{A} + \frac{\hat{B}}{M_j} \]

We use these two estimators to estimate the ratio \( \hat{c}_{jb} \equiv \sqrt{\frac{\text{Var}[W_{j}^R|M_j]}{\text{Var}[W_{j_b}^R|M_{j_b}]}} \). Lemma 4 shows that is \( \hat{c}_{jb} \) is a consistent estimator for \( c_{jb} \).

**Lemma 4** Under assumptions 1, 2, 3 and 4, for our leading example, \( \hat{c}_{jb} \) is a consistent estimator for \( c_{jb} = \sqrt{\frac{\text{Var}[W_{j_b}^R|M_{j_b}]}{\text{Var}[W_{j_b}^R|M_{j_b}]}} \).

**Proof.**

\[ \text{Var} [W_j | M_j] = A + \frac{B}{M_j} \text{ and } \mathbb{E} [W_j | M_j] = 0 \]
So we can write
\[ \mathbb{E} [(W_j)^2 | M_j] = A + \frac{B}{M_j} \]
or
\[ (W_j)^2 = A + \frac{B}{M_j} + \omega \]
where \( \mathbb{E} [\omega | M_j] = 0 \). Using the result of lemma 1 and the continuity theorem, we estimate \( A \) and \( B \) by ordinary least squares regression of \( \hat{W}_j^R \) on a constant, and \( \frac{1}{M_j} \). We obtain consistent estimators as \( N_0 \to \infty \) and \( M_j \) does not vary with \( N_0 \).
A.2 Extension: Two or more treated periods

So far, we consider that that treatment happens only at \( t^* \). Now, we extend the proofs to the case that treatment happens in different periods. We assume that there \( N_0 \) control groups and \( N_k \) treated groups that started treatment at \( t^*_k \), for \( k = 1, \ldots, K \).

We will say that \( j \in N_0 \) to refer to a group \( j \) that belongs to the control group and \( j \in N_k \) with \( k > 0 \) to refer to a treated group \( j \) that started treatment at \( t^*_k \). In this case, \( N = N_0 + \sum_{k=1}^K N_k \).

First, we show that in this case, we can write the estimator \( \tilde{\alpha} \) as a linear combination of

\[
\sum_{k \in N_k} \frac{1}{N} \sum_{t>T_k} Y_{jt} - \frac{1}{N} \sum_{j \in N_0} \nabla^k Y_j,
\]

where \( \nabla^k Y_j = \frac{1}{T_k} \sum_{t>T_k} Y_{jt} - \frac{1}{T_k} \sum_{t\leq T_k} Y_{jt} \). Also, let

\[
W^k_j = \frac{1}{T_k} \sum_{t>T_k} \eta_{jt} - \frac{1}{T_k} \sum_{t\leq T_k} \eta_{jt}.
\]

Define \( \tilde{d}_{jt} \) as

\[
\tilde{d}_{jt} = d_{jt} - \frac{1}{N} \sum_{j' = 1}^N d_{j't} - \frac{1}{T} \sum_{t' = 1}^T d_{j't'} + \frac{1}{N} \sum_{j' = 1}^N \sum_{t' = 1}^T d_{j't'}.
\]

By the Frisch-Waugh-Lovell theorem we know that

\[
\tilde{\alpha} = \frac{\sum_j \sum_t \tilde{d}_{jt} Y_{jt}}{\sum_j \sum_t \tilde{d}_{jt}^2}
\]

We will first analyze the denominator. For \( j \in N_0 \), we have that:

\[
\tilde{d}_{jt} = d_{jt} - \frac{1}{N} \sum_{j' = 1}^K [t > t^*_k] \times N_k - \frac{1}{T} \sum_{t' = 1}^T \sum_{k'} [T-t^*_k] N_{k'}
\]

Since \( \tilde{d}_{jt}^2 \) does not depend on \( j \), then

\[
\sum_{j \in N_0} \tilde{d}_{jt}^2 = \frac{N_0}{N^2} \left[ \frac{1}{T^2} \left( \sum_{k = 1}^K (T-t^*_k) N_k \right)^2 + \left( \sum_{k = 1}^K [t > t^*_k] N_k \right)^2 - \frac{2}{T} \left( \sum_{k = 1}^K (T-t^*_k) N_k \right) \left( \sum_{k = 1}^K [t > t^*_k] N_k \right) \right]
\]

Since \( N_k \) with \( k > 0 \) is fixed, as \( N_0 \to \infty \)

\[
\sum_{j \in N_0} \tilde{d}_{jt}^2 \xrightarrow{N_0 \to \infty} 0
\]

For \( j \in N_k \) with \( k > 0 \) we have

\[
\tilde{d}_{jt} = d_{jt} - \frac{1}{N} \sum_{k' = 1}^K [t > t^*_k] \times N_{k'} - \frac{1}{T} (T-t^*_k) + \frac{1}{NT} \sum_{k' = 1}^K (T-t^*_k) N_{k'}
\]

When \( N_0 \to \infty \):

\[
\tilde{d}_{jt}^2 = \left( d_{jt} - \frac{1}{T} (T-t^*_k) \right)^2
\]

\[
= d_{jt}^2 + \frac{1}{T^2} (T-t^*_k)^2 - 2 \frac{d_{jt}}{T} (T-t^*_k)
\]

(19)

Therefore:

\[
\sum_{t = 1}^T \tilde{d}_{jt}^2 = t^*_k \left( \frac{1}{T^2} (T-t^*_k)^2 \right) + (T-t^*_k) \left( 1 + \frac{1}{T^2} (T-t^*_k)^2 - 2 \frac{1}{T} (T-t^*_k) \right)
\]

\[
= \frac{1}{T^2} \left[ t^*_k (T-t^*_k)^2 + (T-t^*_k) (T-t^*_k)^2 \right] = \frac{t^*_k (T-t^*_k)}{T}
\]

(20)
This implies that the denominator becomes (as \( N_0 \to \infty \)):

\[
\sum_{j=1}^{N} \sum_{t=1}^{T} d_{jt}^2 = \frac{1}{T} \sum_{k=1}^{K} N_k [t_k^* (T - t_k^*)] \tag{21}
\]

Now we will analyze the numerator. For a \( j \in N_0 \), we have that:

\[
d_{jt} = \frac{1}{N T} \sum_{k=1}^{K} (T - t_k^*) N_k - \frac{1}{N} \sum_{k=1}^{K} 1[t > t_k^*] \times N_k \\
= \frac{1}{N} \sum_{k=1}^{K} N_k \left[ \frac{(T - t_k^*)}{T} - 1[t > t_k^*] \right] \tag{22}
\]

\[
\sum_t d_{jt} Y_{jt} = \frac{1}{N} \left( N_1 \left( \frac{T - t_1^*}{T} \right) + \ldots + N_K \left( \frac{T - t_K^*}{T} \right) \right) \sum_{t > t_1^*} Y_{jt} + \\
\frac{1}{N} \left( N_1 \left( \frac{-t_1^*}{T} \right) + N_2 \left( \frac{T - t_2^*}{T} \right) + \ldots + N_K \left( \frac{T - t_K^*}{T} \right) \right) \sum_{t_1^* < t \leq t_2^*} Y_{jt} + \\
\frac{1}{N} \left( N_1 \left( \frac{-t_1^*}{T} \right) + N_2 \left( \frac{-t_2^*}{T} \right) + N_3 \left( \frac{T - t_3^*}{T} \right) + \ldots + N_K \left( \frac{T - t_K^*}{T} \right) \right) \sum_{t_2^* < t \leq t_3^*} Y_{jt} + \\
\vdots \\
\frac{1}{N} \left( N_1 \left( \frac{-t_1^*}{T} \right) + N_2 \left( \frac{-t_2^*}{T} \right) + \ldots + N_K \left( \frac{-t_K^*}{T} \right) \right) \sum_{t_K^* < t} Y_{jt}
\]

\[
= \frac{N_1}{N} \left( \frac{t_1^*}{T} \sum_{t > t_1^*} Y_{jt} - \frac{(T - t_1^*)}{T} \sum_{t \leq t_1^*} Y_{jt} \right) - \ldots - \frac{N_K}{N} \left( \frac{t_K^*}{T} \sum_{t > t_K^*} Y_{jt} - \frac{(T - t_K^*)}{T} \sum_{t \leq t_K^*} Y_{jt} \right) \tag{23}
\]

As \( N_0 \to \infty \):

\[
\sum_{j \in N_0} \sum_t d_{jt} Y_{jt} = \sum_{j \in N_0} \sum_{k=1}^{K} \frac{N_k}{N} \left( \frac{t_k^*}{T} \sum_{t > t_k^*} Y_{jt} - \frac{(T - t_k^*)}{T} \sum_{t \leq t_k^*} Y_{jt} \right)
\]

For \( j \in N_k \) with \( k > 0 \) as \( N_0 \to \infty \): we have:

\[
\tilde{d}_{jt} = d_{jt} - \frac{1}{T} (T - t_k^*) \tag{24}
\]

Then (when \( N_0 \to \infty \)),

\[
\sum_t d_{jt} Y_{jt} = \frac{t_k^*}{T} \sum_{t > t_k^*} Y_{jt} - \frac{(T - t_k^*)}{T} \sum_{t \leq t_k^*} Y_{jt}
\]

Therefore,

\[
\tilde{d}_{jt} = d_{jt} - \frac{1}{T} (T - t_k^*) \tag{24}
\]

Note that

\[
\sum_{k=1}^{K} \frac{N_k[t_k^* (T - t_k^*)]}{\sum_{k'=1}^{K} N_{k'}} \left[ \frac{1}{N_k} \sum_{j \in N_k} \nabla^k Y_j - \frac{1}{N_0} \sum_{j \in N_0} \nabla^k Y_j \right]
\]

\[
= \alpha_0 + \sum_{k=1}^{K} \frac{N_k[t_k^* (T - t_k^*)]}{\sum_{k'=1}^{K} N_{k'}} \left[ \frac{1}{N_k} \sum_{j \in N_k} \tilde{W}_j^k - \frac{1}{N_0} \sum_{j \in N_0} \tilde{W}_j^k \right]
\]

55
In the general case, if we knew the variance of $W^k_j$, then we could generate a bootstrap sample using the re-scaled residuals 
$$\tilde{W}_{j,b}^k = \tilde{W}_{j}^k \sqrt{\frac{\text{Var}[W^k_j|M_j]}{\text{Var}[W^k_j|M_{j,b}]}},$$
and use the residuals $\tilde{W}_{j,b}^k$ to estimate $\hat{\alpha} - \alpha_0$,

$$\hat{\alpha} - \alpha_0 = \sum_{k=1}^{K} \frac{N_k l_k^*(T - t_k^*)}{\sum_{k'=1}^{K} N_{k'} [ l_{k'}^*(T - t_{k'}^*)]} \left[ \frac{1}{N_k} \sum_{j \in N_k} \tilde{W}_{j,b}^k - \frac{1}{N_0} \sum_{j \in N_0} \tilde{W}_{j,b}^k \right]$$

and use the same hypothesis test stated in the previous section. If the variance of $W_j$ is unknown, then we can estimate this variance using theorem 4.

### A.3 Extension: Model with Covariates

In this case, we work with the aggregate model that includes the covariates:

$$Y_{jt} = \alpha d_{jt} + \theta_j + \beta X_{jt} + \gamma_t + \eta_{jt}$$

(25)

where $X_{jt}$ is a $k \times 1$ vector of covariates. We consider the case in which treatment happens only at $t^*$. By the OLS normal equations:

$$\hat{\alpha} = \frac{\sum_j \sum_t \tilde{d}_{jt} (Y_{jt} - \tilde{\beta} X_{jt})}{\sum_j \sum_t \tilde{d}_{jt}^2}$$

and,

$$\hat{\alpha} \xrightarrow{N_0 \to \infty} \sum_{k=1}^{K} \frac{N_k l_k^*(T - t_k^*)}{\sum_{k'=1}^{K} N_{k'} [ l_{k'}^*(T - t_{k'}^*)]} \left[ \frac{1}{N_k} \sum_{j \in N_k} \nabla^k Y^*_j - \frac{1}{N_0} \sum_{j \in N_0} \nabla^k Y^*_j \right]$$

In this case, under $H_0$ and for the treatment group,

$$\nabla^k Y^*_j = \frac{1}{T - t_k^*} \sum_{t > t_k^*} (Y_{jt} - \tilde{\beta} X_{jt}) - \frac{1}{T - t_k^*} \sum_{t \leq t_k^*} (Y_{jt} - \tilde{\beta} X_{jt})$$

$$= \alpha_0 + \left( \bar{\beta} - \beta \right) \left( \frac{1}{T - t_k^*} \sum_{t > t_k^*} X_{jt} - \frac{1}{T - t_k^*} \sum_{t \leq t_k^*} X_{jt} \right)$$

$$+ \frac{1}{T - t_k^*} \sum_{t > t_k^*} \gamma_t - \frac{1}{T - t_k^*} \sum_{t \leq t_k^*} \gamma_t$$

$$+ \frac{1}{T - t_k^*} \sum_{t > t_k^*} \eta_{jt} - \frac{1}{T - t_k^*} \sum_{t \leq t_k^*} \eta_{jt}$$

By proposition 1 in Conley and Taber (2011), $\bar{\beta} \simeq \beta$. Therefore:

$$\hat{\alpha} \xrightarrow{N_0 \to \infty} \alpha_0 + \sum_{k=1}^{K} \frac{N_k l_k^*(T - t_k^*)}{\sum_{k'=1}^{K} N_{k'} [ l_{k'}^*(T - t_{k'}^*)]} \left[ \frac{1}{N_k} \sum_{j \in N_k} W^k_j - \frac{1}{N_0} \sum_{j \in N_0} W^k_j \right]$$

and we have the same result as in the previous section.

### A.4 FGLS Estimation

In this section, we prove the main results of section 3. Under the assumption that the errors are uncorrelated across $j$, the variance/covariance matrix of $\eta_{jt}$ is block diagonal with $T \times T$. We define $\Omega_j$ as one of the blocks. Under assumption 2,
\( y_j = ad_j + \theta_j + \gamma_t + \eta_j \)

where \( y_j \) is a Tx1 vector with \( \{y_{jt}\}^T_{t=1} \), \( d_j \) is a Tx1 vector with \( \{d_{jt}\}^T_{t=1} \) and \( \eta_j \) is a Tx1 vector with \( \{\eta_{jt}\}^T_{t=1} \). The GLS estimator will be based on the following model:

\[
\Omega \left( \tilde{x}_j \right)^{-\frac{1}{2}} y_j = a \Omega \left( \tilde{x}_j \right)^{-\frac{1}{2}} d_j + \Omega \left( \tilde{x}_j \right)^{-\frac{1}{2}} \theta_j + \Omega \left( \tilde{x}_j \right)^{-\frac{1}{2}} \gamma_t + \Omega \left( \tilde{x}_j \right)^{-\frac{1}{2}} \eta_j
\]

Note that the GLS estimator is the Gaussian-Markov estimator in this problem. In other words, it has the lowest variance among all the linear unbiased estimator. The GLS estimator is the unique solution for following the minimization problem:

\[
\Omega(a) = \left\{ \bar{a}(a) = \sum_{t=1}^{T} \sum_{j=1}^{N} a_{jt} y_{jt} : \sum_{t=1}^{T} a_{jt} = 1, \sum_{t=1}^{T} a_{jt} = 0 \text{ for all } j \text{ and } \sum_{j=1}^{N} a_{jt} = 0 \text{ for all } t \right\}
\]

Note that the variance of any estimator in this class is:

\[
\text{Var} [\bar{a}(a) | D, X] = \sum_{j=1}^{N} a_{jt} \Omega \left( \tilde{x}_j \right) a_{jt}
\]

where \( a_j = \begin{bmatrix} a_{1j} \\ \vdots \\ a_{Tj} \end{bmatrix} \). The GLS estimator is the estimator in the class \( \Omega(\bar{a}) \) that has the minimum variance. In other words, it is the estimator that solves the following optimization problem:

\[
\min_{a_1, ... a_N} \sum_{j=1}^{N} a_{jt} \Omega \left( \tilde{x}_j \right) a_{jt} \text{ s.t. } \sum_{t=t^*+1}^{T} a_{jt} = 1, \sum_{t=1}^{T} a_{jt} = 0 \text{ for all } j, \sum_{j=1}^{N} a_{jt} = 0 \text{ for all } t \quad (26)
\]

Let \( \bar{a}(N_0) = (\bar{a}_1(N_0), ..., \bar{a}_N(N_0)) \) be the unique solution of the minimization problem above.

**Lemma 5** Define \( a_1^* \) as the unique solution for following the minimization problem:

\[
\min_{a_1} a_1' \Omega \left( \tilde{x}_1 \right) a_1 \text{ s.t. } \sum_{t=t^*+1}^{T} a_{t1} = 1, \sum_{t=1}^{T} a_{t1} = -1
\]

As \( N_0 \rightarrow \infty \),

\[35\text{We show that the restrictions imposed on the } a_{jt} \text{ are necessary and sufficient for unbiasedness of the linear estimators.}\]

Consider any linear estimator \( \bar{a}(a) = \sum_{t=1}^{T} \sum_{j=1}^{N} a_{jt} y_{jt} \):

\[
E[\bar{a}(a) | D, X] = E \left[ \sum_{t=1}^{T} \sum_{j=1}^{N} a_{jt} y_{jt} \mid D, X \right] = \alpha \left( \sum_{t=1}^{T} \sum_{j=1}^{N} a_{jt} d_{jt} \right) + \sum_{j=1}^{N} \theta_j \sum_{t=1}^{T} a_{jt} + \sum_{j=1}^{N} \gamma_t \sum_{t=1}^{T} a_{jt} + \sum_{t=1}^{T} \sum_{j=1}^{N} a_{jt} E[\eta_{jt} | X, D]
\]

Assuming that \( E[\eta_{jt} | X, D] = 0 \), in order to have an unbiased estimator, we need:

\[
\sum_{t=1}^{T} \sum_{j=1}^{N} a_{jt} d_{jt} = \sum_{t=t^*+1}^{T} a_{t1} = 1, \sum_{t=1}^{T} a_{jt} = 0 \text{ for all } j, \sum_{j=1}^{N} a_{jt} = 0 \text{ for all } t
\]
\[ \tilde{a}_1 (N_0) \xrightarrow{p} a_1^* \text{ and } \tilde{a}_j (N_0) \xrightarrow{p} 0 \text{ for } j = 2, \ldots, N \]

**Proof.** By contradiction, suppose that \( \tilde{a}_1 (N_0) \) does not converge in probability to \( a_1^* \). If this is the case, \( \exists \varepsilon > 0 \) and \( c_1 > 0 \) such that \( \Pr \left[ | \tilde{a}_1 (N_0) - a_1^* | > \varepsilon \right] \geq c_1 \forall N_0 \). For every \( \tilde{a}_1 (N_0) : | \tilde{a}_1 (N_0) - a_1^* | > \varepsilon \), we have that

\[ \tilde{a}_1 (N_0) \Omega \left( \tilde{X}_1 \right) \tilde{a}_1 (N_0) - a_1^* \Omega \left( \tilde{X}_1 \right) a_1^* \geq c_2 \]

for some positive constant \( c_2 \). One possible solution for the minimization problem 26 is:

\[ a_1 = a_1^* \text{ and } a_j = - \frac{a_1^*}{N-1} \]

This solution satisfies all the constraints in the minimization problem, including the restriction that \( a_{1t} = - \sum_{j=2}^{N} a_{jt} \) for all \( t \). Therefore, we have an upper bound for the optimization function when \( N_0 \to \infty \),

\[ \tilde{a}_1 (N_0) \Omega \left( \tilde{X}_1 \right) \tilde{a}_1 (N_0) \leq \tilde{a}_1 (N_0) \Omega \left( \tilde{X}_1 \right) \tilde{a}_1 (N_0) + \sum_{j=2}^{N} a_j^* (N_0) \Omega \left( \tilde{X}_j \right) a_j (N_0) \]

\[ \leq a_1^* \Omega \left( \tilde{X}_1 \right) a_1^* + \frac{1}{(N-1)^2} \sum_{j=2}^{N} a_j^* \Omega \left( \tilde{X}_j \right) a_1^* \]

So by the expression above,

\[ \tilde{a}_1 (N_0) \Omega \left( \tilde{X}_1 \right) \tilde{a}_1 (N_0) - a_1^* \Omega \left( \tilde{X}_1 \right) a_1^* \leq \frac{1}{(N-1)^2} \sum_{j=2}^{N} a_j^* \Omega \left( \tilde{X}_j \right) a_1^* = o_p(1) \]

However, as we showed before if \( \tilde{a}_1 (N_0) \) does not converge in probability to \( a_1^* \), \( \tilde{a}_1 (N_0) \Omega \left( \tilde{X}_1 \right) \tilde{a}_1 (N_0) - a_1^* \Omega \left( \tilde{X}_1 \right) a_1^* \geq c_2 \)

for some positive constant \( c_2 \). So, by contradiction,

\[ \tilde{a}_1 \xrightarrow{p} a_1^* \]

Using this result, the value of the objective function that we are minimizing when \( N_0 \to \infty \) is:

\[ a_1^* \Omega \left( \tilde{X}_1 \right) a_1^* + \sum_{j=2}^{N} a_j^* (N_0) \Omega \left( \tilde{X}_j \right) a_j (N_0) \leq a_1^* \Omega \left( \tilde{X}_1 \right) a_1^* + o_p(1) \]

so the best choice of \( a_j (N_0) \) is one that converges in probability to zero as \( N_0 \to \infty \). □

By Lemma 5, we have that

\[ \tilde{\alpha}_{GLS} - a_0 \to_d \sum_{t=1}^{T} \alpha_{tt} \eta_{tt} \]

**Assumption 5(Consistent Variance Matrix):** There is an estimator \( \tilde{\Omega} \left( \tilde{X}_j \right) \) that converges in probability to a positive semidefinite matrix, called \( \Omega \left( \tilde{X}_j \right) \).

Now, we work a FGLS estimator using \( \tilde{\Omega} \left( \tilde{X}_j \right) \) as an estimator for \( \Omega(\tilde{X}_j) \). The FGLS estimator will converge to

\[ \tilde{\alpha}_{FGLS} - a_0 \to_d \sum_{t=1}^{T} \alpha_{tt} \eta_{tt} \]

58
We combine our method with FGLS by using \( W_j^* = \sum_{t=1}^{T} \pi_{it} \eta_{jt} \). In order to apply our method, we need to impose assumptions 1-4 on the behavior of \( W_j^* \):

1* \( \{ W_j^* , X_j \} \) is i.i.d across \( j \in \{ 1, ..., N_1 \} \), i.i.d across \( j \in \{ N_1 + 1, ..., N \} \) and independently distributed across \( j \in \{ 1, ..., N \} \).
2* \( W_j^* | X_j, d_j \overset{d}{=} W_j^* | \tilde{X}_j \).
3* \( W_j^* | \tilde{X}_j \) has the same distribution across \( \tilde{X}_j \) up to a scale parameter.
4* \( E [ W_j^* | X_j, d_j ] = E [ W_j^* | X_j ] = 0. \)

These assumptions can be implied by primitive conditions on \( \eta_{jt}, \) for \( j = 1, ..., N \) and \( t = 1, ..., T \).

In our leading example,

\[
\text{Var} [ W_j^* | X_j, d_j ] = \text{Var} [ W_j^* | M_j ] = A^* + \frac{B^*}{M_j}
\]

where \( A^* \) and \( B^* \) will depend on \( \{ \pi_{it} \}_{t=1}^{T} \) and the variance-covariance matrix of \( \eta_{jt} \).

We apply our method to \( W_j^* = \sum_{t=1}^{T} \pi_{it} \eta_{jt} \). For each control unit, we construct \( \tilde{W}_{j,b}^R = \sum_{t=1}^{T} \tilde{\alpha}_{i,b} \eta_{jt} \) using the estimator of the variance-covariance matrix, \( \tilde{\Omega} (\tilde{X}_j) \). Then, we generate a bootstrap sample of \( \{ \tilde{W}_{j,b}^R \} \). As in the main procedure, we generate the normalized \( \tilde{W}_{j,b}^* = \frac{\tilde{W}_{j,b}^R}{\sqrt{\text{Var} [ W_j^* | X_j ]}} \), and then we generate a bootstrap sample using the re-scaled residuals,

\[
\tilde{W}_{j,b}^* = \tilde{W}_{j,b}^R \cdot \sqrt{\text{Var} [ W_j^* | \tilde{X}_j ]}.
\]

This procedure generates bootstrap estimators, \( \tilde{\alpha}_{FGLS,b} - \alpha_0 = \tilde{W}_{j,b}^* \).

We reject \( H_0 \) at level \( \alpha \) if and only if \( \tilde{\alpha}_{FGLS} - \alpha_0 < \left( \tilde{\alpha}_{FGLS,b} - \alpha_0 \right) \left[ \frac{q}{2} \right] \) or \( \tilde{\alpha}_{FGLS} - \alpha_0 > \left( \tilde{\alpha}_{FGLS,b} - \alpha_0 \right) \left[ 1 - \frac{q}{2} \right] \), where \( \left( \tilde{\alpha}_{FGLS,b} - \alpha_0 \right) [q] \) denotes the \( q \)th quantile of the distribution of \( \{ (\tilde{\alpha}_{FGLS,b} - \alpha_0), ..., (\tilde{\alpha}_{FGLS,b} - \alpha_0) \} \).

**Theorem 6** Define \( c_1 - \frac{q}{2} \) and \( c_2 \) as the \( 1 - \frac{q}{2} \)th and \( \frac{q}{2} \)th quantile of the empirical distribution of \( \tilde{\alpha}_{FGLS,b} - \alpha_0 \) given \( X \), for \( b = 1, ..., B \). Assuming that we know the variance of \( W_j^* | \tilde{X}_j \), under assumptions 1*-4*,

\[
\Pr \left[ c_1 - \frac{q}{2} \leq \tilde{\alpha}_{FGLS,b} - \alpha_0 \leq c_2 \right] \rightarrow_{p} 1 - \alpha
\]

**Proof.** The proof is very similar to the proof of Theorem 2, so we skip some steps. First, we need to show that \( \Gamma_b^* = \Pr [ \tilde{W}_{j,b}^* < w | \tilde{X}_j, b ] \) converges in probability to \( \Gamma^* = \Pr [ W_j^* < w | \tilde{X}_1 ] \). Under assumption 1*,

\[
\Gamma_b^* = \int 1 \{ W_j^* < w \} \cdot d\tilde{F}_{j|\tilde{X}_j} (W_j^*)
\]

\[
\Gamma^* = \int 1 \{ W_j^* < w \} \cdot dF_{j|\tilde{X}_j} (W_j^*)
\]

In this case, we estimate the empirical CDF \( \tilde{F}_{j|\tilde{X}_j} (w) \) using the re-scaled residuals, \( \tilde{W}_{j,b}^* = \frac{\tilde{W}_{j,b}^R}{\sqrt{\text{Var} [ W_j^* | X_j ]}} \),

\[
\tilde{F}_{j|\tilde{X}_j} (w) = \frac{1}{B} \sum_{b=1}^{B} \mathbb{1} \{ \tilde{W}_{j,b}^* < w \}
\]

Define \( F_{j|\tilde{X}_j} (w) = \frac{1}{B} \sum_{b=1}^{B} \mathbb{1} \{ W_{j,b}^* < w \} \), where \( W_{j,b}^* = \frac{\tilde{W}_{j,b}^R}{\sqrt{\text{Var} [ W_j^* | X_j ]}} \) with \( \tilde{W}_{j,b}^R \) comes from a bootstrap sample of \( \{ \tilde{W}_{j,b}^R \} \).
First, notice that in our case, the inference procedure is respect to one dimensional parameter, however, we can extend all the results to the case of few treated groups (more than one).

Test (UMP) for two sided alternative. In addition, since the GLS is the Gauss-Markov estimator, under normality the t-test will exist for one sided alternative, and uniformly most powerful unbiased test (UMPEC). Under assumptions 1-6, if

\[ \text{Theorem 7} \]

Proof. Without loss of generality, we are going to look to the following one-sided test:

\[ H_0 : \alpha \leq \alpha_0 \text{ and } H_1 : \alpha > \alpha_0 \]

Since we are considering, for simplicity, the case with only one treated group, then, under assumptions 1 and 6:

\[ \hat{\alpha}_{GLS} - \alpha_0 \to_d N\left(0, (\sigma_1^*)^2\right) \]

where \( \sigma_1^* = \sqrt{\text{var}(W_1^1|X_1)} \).

For a fixed alternative, the power of a t-test based on the unfeasible GLS is:

\[ \beta^*(\alpha) = \Pr\left[\left(\frac{\hat{\alpha}_{GLS} - \alpha_0}{\sigma_1^*}\right) > z_{1-\alpha}\right] = \Pr\left[\left(\frac{\hat{\alpha}_{GLS} - \alpha}{\sigma_1}\right) > z_{1-\alpha} - \frac{\alpha - \alpha_0}{\sigma_1^*}\right] \]

Notice that, under assumptions 1-6, if \( \Omega\left(\vec{X}_j\right) = \Omega\left(\vec{X}_j\right) \), then:

\[ \hat{\alpha}_{FGLS} - \alpha_0 \to_d N\left(0, (\sigma_1^*)^2\right) \]

Let \( c_{1-\alpha} = \left(\hat{\alpha}_{FGLS,b} - \alpha_0\right)[1 - \alpha] \). Then, under fixed alternatives, the power of the procedure that combines FGLS with
\[ \beta(\alpha) = \text{Pr}\{ \hat{\alpha}_{\text{FGLS}} - \alpha > c_{1-\alpha} - (\alpha - \alpha_0) \} \]

\[ = \text{Pr}\left\{ \frac{\hat{\alpha}_{\text{FGLS}} - \alpha}{\hat{\sigma}_1^*} > \frac{c_{1-\alpha} - (\alpha - \alpha_0)}{\hat{\sigma}_1^*} \right\} \]

Since \( \hat{\alpha}_{\text{FGLS}} - \alpha = o_p(1) \), then it suffices to show that \( \frac{c_{1-\alpha}}{\hat{\sigma}_1^*} \rightarrow_p \sqrt{1-\alpha} \) even under the alternative to show that \( \beta(\alpha) \rightarrow_p \beta^*(\alpha) \).

We argue first that, under the alternative, \( \sup_{w_j \in \mathcal{W}} \left| \hat{F}_{\text{resample}}^{\ast - 1}(w_j) - F_{\text{resample}}^{\ast - 1}(w_1) \right| = o_p(1) \). Notice that \( \hat{W}_{j,t}^{*R} \rightarrow_d W_{j,t}^{*} \) for all \( j \) in the control group, even if the null is false. Now notice that, with a small and fixed number of treated groups, the probability of resampling a treated group converges to zero as \( N_0 \rightarrow \infty \). Therefore, our Theorem 6 would apply even under the alternative. Finally, since, under normality, the quantiles of \( \hat{\alpha}_{\text{FGLS}} \) are well defined, then we can apply the continuity theorem to show that \( \frac{c_{1-\alpha}}{\hat{\sigma}_1^*} \) converges in probability to \( \sqrt{1-\alpha} \).

Finally, we consider the estimation of \( \hat{\sigma}_1(\tilde{X}_j) \) in our leading example in which heteroskedasticity is generated by variation in group sizes, so \( \eta_{jt} \) is defined as in formula 8. We first show that the estimator of the AR parameters do not have the linearity that Hansen (2007) uses to derive the bias and provide his bias correction. Then we show that it would be possible to consistently estimate \( \hat{\Omega}(\tilde{X}_j) \) if we impose stronger assumptions on the errors. This is important because the hypothesis testing with the FGLS estimator relies on the consistency of the \( \hat{\Omega}(\tilde{X}_j) \) estimator. Therefore, combining our inference method with FGLS provides a safeguard in case \( \hat{\Omega}(\tilde{X}_j) \) is not consistent.

For simplicity, assume that the number of observations is constant across time for each group \( \{M(j,t) = M_j\} \) and that \( \nu_{jt} \) and \( \epsilon_{ijt} \) follow an AR(1) process with parameters \( \rho_{\nu} \) and \( \rho_{\epsilon} \). We also assume that \( \epsilon_{ijt} \) is i.i.d. across \( i \). In this case, the diagonal elements of \( \hat{\Omega}(M_j) \) would be given by \( \sigma_{\epsilon}^2 + 1/T \sigma_{\nu}^2 \) while the non-diagonal elements would be given by \( \rho_{\nu} \sigma_{\epsilon}^2 + 1/T \rho_{\epsilon}^2 \sigma_{\nu}^2 \). Note that, differently from Hansen (2007) who assumes that the model is homoskedastic, we need to consistently estimate \( \rho_{\nu} \), \( \sigma_{\nu}^2 \), \( \rho_{\epsilon} \) and \( \sigma_{\epsilon}^2 \). If we could observe \( \nu_{jt} \), then we could estimate all these parameters using a non-linear least squares estimates, given that \( E[\nu_{jt}\nu_{jt'}|M_j] = \rho_{\nu}^{t-t'}\sigma_{\nu}^2 + 1/T \rho_{\epsilon}^{t-t'}\sigma_{\epsilon}^2 \). The problem, however, is that we can only observe \( \bar{\eta}_{jt}, \frac{d}{T} \sum_{t=1}^{T} \eta_{jt}, \) which implies that:

\[ E[\bar{\eta}_{jt}\bar{\eta}_{jt'}|M_j] = \left( \rho_{\epsilon}^{t-t'}\sigma_{\epsilon}^2 \right) - \frac{1}{T} \sum_{t=1}^{T} \left( \rho_{\nu}^{t-t'} + \rho_{\epsilon}^{t-t'} \right) \sigma_{\nu}^2 + \frac{1}{M_j} \left( \rho_{\nu}^{t-t'} + \rho_{\epsilon}^{t-t'} \right) \sigma_{\nu}^2 \]

Therefore, the non-linear least squares estimator would be biased when \( T \) is fixed. Moreover, we do not have the linearity that Hansen (2007) uses to derive the bias and provide the bias correction.

If we assume that all serial correlation comes from \( \epsilon_{ijt} \), then we would have that:

\[ Y_{ijt} - \frac{1}{M_j} \sum_{i=1}^{M_j} Y_{ijt} = \epsilon_{ijt} - \frac{1}{M_j} \sum_{i=1}^{M_j} \epsilon_{ijt} \]

If \( M_j \) is large, then \( Y_{ijt} - \frac{1}{M_j} \sum_{i=1}^{M_j} Y_{ijt} \rightarrow_d \epsilon_{ijt} \). We do not have a problem of incidental parameter here. Therefore, we can regress \( Y_{ijt} - \frac{1}{M_j} \sum_{i=1}^{M_j} Y_{ijt} \) on \( Y_{ijt-1} - \frac{1}{M_j} \sum_{i=1}^{M_j} Y_{ijt-1} \) to get consistent estimators for \( \rho_{\nu} \). The diagonal elements of \( \hat{\Omega}(M_j) \)

\[ 36 \text{In Hansen (2007), } \hat{\Omega} = \sigma_\eta^2 \Sigma \text{ where } \Sigma \text{ only depends on the AR(p) parameters. Therefore, he does not need to estimate } \sigma_\eta^2 \text{ to construct the FGLS estimator.} \]
are given by $\sigma^2 + \frac{1}{M_j} \sigma^2$ while the off-diagonal elements are given by $\frac{1}{M_j} \rho \sigma^2$. Note that:

$$\frac{1}{T} \sum_{t=1}^{T} \frac{1}{N} \sum_{j=1}^{N} \frac{1}{M_j} \sum_{i=1}^{M_j} \left( Y_{i,j,t} - \frac{1}{M_j} \sum_{i=1}^{M_j} Y_{i,j,t} \right)^2 \to \sigma^2$$

We still need to estimate the diagonal elements. We can do that looking at $\hat{\eta}^2_{jt}$. Note that:

$$\hat{\eta}^2_{jt} \to_d \eta^2_{jt} - \frac{1}{T} \sum_{t'=1}^{T} \eta_{t'}$$

$$= \nu_{jt} - \frac{1}{T} \sum_{t'=1}^{T} \nu_{jt'} + \frac{1}{M_j} \sum_{i=1}^{M_j} \left[ \epsilon_{i,j,t} - \frac{1}{T} \sum_{t'=1}^{T} \epsilon_{i,j,t'} \right]$$

$$= \frac{T-1}{T} \nu_{jt} - \frac{1}{T} \sum_{t' \neq t} \nu_{jt'} + \frac{1}{M_j} \sum_{i=1}^{M_j} \left[ \epsilon_{i,j,t} - \frac{1}{T} \sum_{t'=1}^{T} \epsilon_{i,j,t'} \right]$$

Therefore, since we are assuming that all serial correlation comes from $\epsilon$, then:

$$E \left[ \hat{\eta}^2_{jt} \right] = \left[ \frac{(T-1)(T-2)}{T^2} \right] \sigma^2 + \Gamma(\rho, \sigma^2)$$

where $\Gamma(\rho, \sigma^2)$ is known function of $\rho_e$ and $\sigma^2_e$. Since we have consistent estimators for both $\rho_e$ and $\sigma^2_e$, we can get an unbiased estimator for $\sigma^2_e$.
