Empirical Reassessment of Bank-based Financial Development and Economic Growth in Hong Kong

Abstract

This paper reassesses the nexus between bank-based financial development and economic growth in Hong Kong during the period 1990–2014. That is, it tests whether Hong Kong follows a supply-leading or a demand-following hypothesis. Empirically, economists have generally disagreed on the nexus between bank-based financial development and economic growth. Hong Kong is a typical economy which has experienced both bank-based financial expansion and economic expansion in the last three decades. It therefore serves as a quintessence for testing this overarching debate. Using the Toda-Yamamoto test for causality and two indicators of bank-based financial development – in order to report robust results – the paper finds Hong Kong to follow the supply-leading hypothesis. This implies that the banking sector is vital in driving economic growth in Hong Kong during the study period. Policymakers in this economy will only enhance economic growth further by targeting and ensuring efficient performance of bank-based financial institutions.

Keywords: Bank-based Financial Development; Economic Growth; Causality; Hong Kong

1. Introduction

Do banking systems drive economic growth? Or does economic growth drive banking systems? These questions have been prominent at least since the nineteenth century. Among the earliest economists to assess the relationships between financial systems and economies is Schumpeter (1912). In his paper, he emphasises the importance of the banking sector in aiding technological innovation and productive investment, which eventually drives economic growth. In contrast to Schumpeter (1912), Robinson (1952) asserts that financial development has no influence on economic growth. She argues, instead, that economic growth influences the development of financial markets. Robinson (1952) argues that as economies grow the need for financial services arises, thereby stimulating the growth of financial systems.

Since the above seminal works, various studies have analysed, extensively, the linkages between financial development and economic growth. In characteristic fashion, the empirical results remain divergent. In this paper, instead of focusing on the broad concept of financial development – which can be classified into bank-based and market-based financial development – we concentrate on bank-based financial development. In general, the findings in the literature can at best be classified into four broad categories. The first is the so-called finance-led growth hypothesis, whereby bank-
based financial development acts as a precursor to economic growth. Several empirical studies are consistent with this view. See among others, Bittencourt (2012), Chaiechi (2012), Lee (2012), and Colombage (2009). The second is the so-called growth-led finance hypothesis, whereby economic growth acts as a precursor to bank-based financial development. This view has been supported in studies such as Hassan et al. (2011), Colombage (2009), Chakraborty (2008), and Zang and Kim (2007). The third category finds bidirectional causality between bank-based financial development and economic growth. This has been corroborated in studies such as Bangake and Eggoh (2011), Hassan et al. (2011), Wolde-Rufael (2009), Abu-Bader and Abu-Qarn (2008), and Hondroyiannis et al. (2005). The fourth category finds no causality between bank-based financial development and economic growth. Studies such as Ibrahim (2007), Chang (2002), and Shan et al. (2001) find support for this view.

Most of these studies are either based on bivariate frameworks, cross-sectional approaches, or on frameworks that suffer from small sample properties. This paper attempts to re-assess the causal linkage between bank-based financial development and economic growth in Hong Kong, using a testing technique that overcomes the afore-mentioned shortcomings of the previous studies. We achieve this aim by extracting indicators of bank-based financial development and economic growth, and by building an augmented vector autoregression (VAR) model which caters for variable omission by introducing inflation. Then, by applying the Toda-Yamamoto test, we find Hong Kong to follow the supply-leading hypothesis. This implies that the banking sector is an important source of economic growth in Hong Kong during the study period. Based on this conclusion, we argue that policymakers in this economy will only enhance economic growth further by targeting and ensuring efficient performance of bank-based financial institutions.

The rest of the paper is organised as follows. In the next section, we discuss the trends in banking development and economic growth in Hong Kong. Section 3 gives the theoretical and empirical underpinning of the finance-growth nexus. Section 4 outlines the empirical methodology and the data. Section 5 analyses the empirical results. Section 6 provides the conclusion.

2. Banking sector development and economic growth in Hong Kong

At the beginning of the twentieth century, Hong Kong was merely a barren land. Today, the economy of Hong Kong is one of the most advanced in the world. In 1842, when Britain took over, Hong Kong was the central trading port for South China and the Chinese community overseas. Although industrialisation in Hong Kong had started before the Pacific War, the government mainly focused on trade, with only limited attention to domestic manufacturing activities (Tsang, 2004). However, the civil war, which broke out in mainland China during this period leading to the victory of the Communist party in 1949, triggered massive inflow of labour, capital, and entrepreneurial skills from Shanghai to Hong Kong. These incidents led to the fundamental changes in Hong Kong. As a result, the economy of Hong Kong transformed from its long-established position as China’s main entrepôt to a highly industrialised city (Krause, 1988; Tsang, 2004). The post-war era witnessed the establishment of large export-dependent local manufacturing sectors in Hong Kong. From the 1980s onwards, the economy shifted gradually from manufacturing into banking and financial services (see Young, 1992). Over the course of three decades, Hong Kong has transitioned from a manufacturing base to become one of the leading global financial centres (see Taylor, 2005; Meyer, 2015). Overall, Hong Kong has attained
tremendous economic expansion during the past three decades. Today, Hong Kong together with Singapore, South Korea, and Taiwan, are known as the four Asia tigers. Hong Kong is also part of the so-called new industrialised countries of the East.

The economy of Hong Kong boasts of an advanced banking sector, which has created a wide range of financial products and services. The concentration of banking institutions in Hong Kong is one of the highest in the world. More than 70 of the world’s largest 100 banks have operations in Hong Kong [Hong Kong Monetary Authority (HKMA), 2016]. Hong Kong now has a three-tier banking system, which is made up of deposit-taking companies, restricted licensed banks, and licensed banks. The chief regulator of the banking system in Hong Kong is the Hong Kong Monetary Authority (HKMA, 2016). Altogether, there are 199 authorised institutions (i.e. the official name of depository institutions under the three-tier system), and 64 local representative offices in Hong Kong. The authorised institutions consist of 157 licensed banks, 24 restricted licensed banks and 18 deposit-taking companies (see HKMA, 2015).

Various structural reforms, events, banking consolidation, and policy initiatives have helped transformed Hong Kong’s banking system in the past three decades. The first significant reform entails shifting from a monolithic system to a three-tier banking system in 1981. A further enhancement occurred in 1990 (see Jao, 2003). Under this system, the first, second and third tiers comprise, respectively, licensed banks, restricted licensed banks and deposit-taking companies. The nature of prudential supervision varies directly with the scope of the banking activity. The strictly regulated banks (i.e. the licensed banks) are allowed to accept all types of deposits. In the case of the second and third tiers, regulation is less-strict, and deposits are confined to time deposits (see Jao, 2003).

The Hong Kong Monetary Authority was created through the merger of the Exchange Fund and the Commissioner of Banking Offices in 1993 and charged with the responsibility of ensuring banking and currency stability. In fact, it was to become the central bank of Hong Kong (see Kwan, 2003). Until the 1990’s, the domestic banking sector was a closely regulated and largely protected sector. For example, the overseas-incorporated banks licensed in and after 1978 and the overseas-incorporated restricted licensed banks authorized in and after 1990 were restricted to operate in one branch, to prevent over-crowding in the retail banking market. As such, locally incorporated banks were relatively protected from foreign competition (Hua and Randhawa, 2006). In addition, the Hong Kong Association of Banks (HKAB), under HKAB ordinance, used a set of interest rate rules to regulate interest rates on bank deposits since 1964 (Kwan, 2003).

In the 1990s, authorities in Hong Kong implemented various initiatives to stimulate competition in the banking system. Among them were the deregulation of interest rates, the relaxation of one branch policy for foreign banks, and the relaxation of the market-entry criteria. The set of interest rate rules that were used to regulate the interest rates on bank deposits were eventually relaxed in 1994. This was achieved through the removal of the ceiling on interest rates put on certain types of time deposits (Kwan, 2003). The monetary authority outlined steps to remove the interest rate rules entirely after the Asian financial crisis in order to promote competition. The Hong Kong Monetary Authority completed its extensive deregulation of interest rates in 2001 (Kwan, 2003). In a bid to ensure equal chance for all participants (local and foreign), the monetary authority partially relaxed its one-branch restriction for foreign banks and introduced a three-branch
condition in 1999 (see Jiang et al., 2003). In 2001, the monetary authority successfully removed all limitations on the number of branches and offices for foreign banks. In addition to this, the market-entry criteria were relaxed in 2002, permitting foreigners to invest in the local banking system (Jiang et al., 2003). As part of these market-entry initiatives, the asset-size requirement for foreign banks was reduced. The requirements for the domestically incorporated restricted licensed banks and deposit-taking companies to upgrade to licensed-bank status were also relaxed (Jiang et al., 2003). The aim of these initiatives was that by gradually eliminating market-entry barriers, the market can determine the optimal number of institutions in the banking sector (see Hua and Randhawa, 2006).

The extensive financial liberalisation initiatives, a steady technological progress, costs cutting initiatives and a steady growth of revenue led to huge bank consolidation in Hong Kong. During the 2000s, a host of mergers and acquisitions took place in the banking system. As a consequence, the number of licensed banks dropped from 31 in 2000 to 23 in 2007 (see HKMA, 2001; 2007). In 2001, the ten member banks of the Bank of China Group consolidated into the Bank of China (Hong Kong); and in July 2002, the bank got listed on the Hong Kong stock exchange (Jiang et al., 2004). Foreign banks have undertaken deals with smaller banks in Hong Kong in order to gain access to the mainland China market (see Jiang et al., 2004). In addition, the number of authorised institutions has declined by 45% (i.e. from 361 to 199 during the period 1997 to 2015) [HKMA, 1997; 2015], following the restructuring of foreign parent banks and the consolidation of overseas banks during the Asian financial crisis.

Generally, the banking system in Hong Kong has developed considerably during the past three decades. To make this point clear, let us take a look at two proxies of banking sector development, namely: Private Credit by Deposit Money Banks as a percentage of GDP (PC/GDP) and Bank Deposits as a percentage of GDP (BD/GDP). Figure 1 shows that PC/GDP first fell from 153% in 1990 to 124% in 1993, and then increased gradually to 175% in 1998. There was a downward adjustment in the PC/GDP, following the Asian financial crisis, the burst in the technology bubble, the terrorist attack in the United States, and the effect of epidemic virus; the PC/GDP dropped to 142% in 2004. After the slow recovery of the recent global financial crisis, there was a marked improvement in the banking sector development during the period of 2010 to 2014, with the highest PC/GDP value (i.e. 219%) being recorded in 2014 (Global Financial Development Database, 2016). In addition, if the banking sector development is proxy by Bank Deposits as a percentage of GDP (BD/GDP), the development of the banking system in Hong Kong looks even more impressive (see Figure 1). The BD/GDP shows a general upward trend from 160% to 331% during the period of 1990 to 2014 (Global Financial Development Database, 2016).

The banking sector expansion was associated with the expansion of the real sector. As Figure 1 shows, real GDP per capita has experienced nearly twofold increment over the past two decades (i.e. from US$ 17566 in 1990 to US$ 34222 in 2014). On the average, real GDP per capita growth was around 2.3% in the 1990s, and around 3.5% in the 2000s. However, the economic growth slowed down to 2.2% in the first half of 2010s (Global Financial Development Database, 2016).

3. Literature Review

The causal nexus between financial development and economic growth has remained a topical issue for several years. By and large, the theoretical and empirical literature has been divisive as to whether financial development precedes economic growth or economic growth is a precursor to financial development. According to Schumpeter (1912), financial development fosters technological innovations and economic growth through the mobilization of funds, risks management, evaluation and selection of projects, facilitation of transactions, and the monitoring of entrepreneurs. Goldsmith (1969) attributes the positive association between finance and growth to efficient capital stock usage. McKinnon and Shaw (1973) note that financial development enhances growth by enhancing the productivity of capital. To them, a well-developed financial system is necessary for the attainment of economic growth.

In contrast, other economists remain unconvinced by the role played by financial development in economic growth. Robinson (1952), for instance, notes that financial development cannot influence economic growth. To her, financial development is a by-product of economic growth. In her view, economic growth breeds the need for financial products and services. This in turn necessitates the development of financial institutions and intermediaries. Lucas (1988) agrees with this notion by asserting that the role played by the financial sector in economic growth has been overstated. He argues that the financial sector develops in response to economic growth.

Patrick (1966) attempts at reconciling these views by contending that at the early stage of economic development, financial development promotes economic growth, while at the latter stage of economic development, growth tends to promote further financial development. In other words,
he argues that there exists bidirectional causality between financial development and economic growth. In contrast, Graff (1999) argues that financial development and economic growth are not causally related. To him, what appears to be a link between the two variables is nothing but a result of a historical anomaly.

On the empirical front, the findings in the literature can at best be classified into four broad categories. The first is the so-called finance-led growth hypothesis, whereby bank-based financial development causes economic growth. Several empirical studies are consistent with this view. See among others, Phiri (2015), Sehrawat and Giri (2015), Menyah et al. (2014), Hsueh et al. (2013), Bittencourt (2012), Chaiachi (2012), Lee (2012), Colombage (2009), Habibullah and Eng (2006), Chang and Caudill (2005), Calderón and Liu (2003), Agbetsiafa (2003), Rousseau and Wachtel (2000), Choe and Moosa (1999), Darrat (1999), Ahmed and Ansari (1998), and Jung (1986). The second is the so-called growth-led hypothesis, whereby economic growth causes bank-based financial development. This view has been supported in studies such as Menyah et al. (2014), Hassan et al. (2011), Colombage (2009), Chakraborty (2008), Zang and Kim (2007), Ang and McKibbin (2006), Liang and Teng (2006), Thangavelu et al. (2004), Waqabaca (2004), Agbetsiafa (2003), Shan et al. (2001), Demetriades and Hussein (1996), and Jung (1986), among others. The third argues for bidirectional causality between bank-based financial development and economic growth. This has been corroborated in studies such as Pradhan et al. (2014), Bangake and Eggoh (2011), Hassan et al. (2011), Wolde-Rufael (2009), Abu-Bader and Abu-Qarn (2008), Hondroyiannis et al. (2005), Calderón and Liu (2003), Shan et al. (2001), and Demetriades and Hussein (1996). The fourth argues for no causality between bank-based financial development and economic growth. This view has been supported by studies such as Menyah et al. (2014), Ibrahim (2007), Chang (2002), and Shan et al. (2001). In Table 1, we provide a detailed breakdown of the empirical studies. It is clear from Table 1 that the literature is inconclusive. The inconclusive nature of the literature necessitates our paper.

### 4. Methodology and Data

In this section, we present the data, the econometric techniques, and the empirical models utilised to investigate the causal linkages between bank-based financial development and economic growth in Hong Kong. To examine the stationary properties of the indicators of bank-based financial development and economic growth, we use the Augmented Dickey-Fuller (ADF), and the Dickey-Fuller generalised least squares (DF-GLS) tests. We then test whether bank-based financial development and economic growth are causally related by employing the Toda-Yamamoto test.
4.1 Testing for Stationarity

Our first step in the empirical analysis is to assess the stationary properties of the variables. For this purpose, we utilize the ADF and DF-GLS tests to examine the stationary properties of the variables. We employ the DF-GLS test as a robust alternative the ADF test, which is known to over-reject the hypothesis of no stationarity (see Schwert, 1986; Caner and Killian, 2001). According to Elliot et al. (1996), the DF-GLS test has substantially higher power even in situations where the root of the series is nearly one. The choice of lags is crucial in stationarity testing. In this paper, we use the Modified Akaike Information Criterion (MAIC) to choose the optimal lags to be included in the auxiliary regressions. The auxiliary regressions as well as the test statistics under the ADF and DF-GLS tests are well documented in the literature. We do not focus on them in this paper.

4.2 Granger Causality Testing using the Toda-Yamamoto Test

The traditional approach for causality testing as proposed by Granger (1969) entails that we establish the integration properties of the variables under consideration. If the variables are integrated, we must examine the possibilities of cointegrating relationships, before we can carry out the test for causality. This becomes problematic because majority of the diagnostic tests for non-stationarity and cointegration are known to have low power against the alternative hypotheses of stationarity and cointegration (see Ho and Iyke, 2016, for similar explanation). In fact, Toda and Yamamoto (1995) have emphasized that the conventional approach to testing for causality – which requires one to test for stationarity and cointegration – is vulnerable to pretesting bias. In support of this view, He and Maekawa (1999), explain that if causality is tested in situations whereby one or both time series are non-stationary, the results would be spurious.

According to Toda and Yamamoto (1995), the problems associated with the conventional test for causality may be obviated by fitting an augmented VAR model, whereby the highest order of integration of the variables is added to the optimal lag of the VAR model. The associated test statistic for the causality test, following this VAR model would have a standard asymptotic distribution (Toda and Yamamoto, 1995). Following Yamada (1998), and Ho and Iyke (2016), a modified vector autoregressive model, $VAR(m + d_{max})$, for testing Granger causality using the Toda-Yamamoto technique will be of the form

$$y_t = y_0 + \sum_{i=1}^{m} y_{1i}y_{t-i} + \sum_{i=m+1}^{m+d_{max}} y_{2i}y_{t-i} + \sum_{i=1}^{m} \phi_{1i}x_{t-i} + \sum_{i=m+1}^{m+d_{max}} \phi_{2i}x_{t-i} + u_{1t} \quad (1)$$

$$x_t = \theta_0 + \sum_{i=1}^{m} \theta_{1i}x_{t-i} + \sum_{i=m+1}^{m+d_{max}} \theta_{2i}x_{t-i} + \sum_{i=1}^{m} \delta_{1i}y_{t-i} + \sum_{i=m+1}^{m+d_{max}} \delta_{2i}y_{t-i} + u_{2t} \quad (2)$$

where $y_t$ and $x_t$ denote the variables; $\delta$, $\gamma$, $\Theta$ and $\varphi$ denote the coefficients; $u_1$ and $u_2$ denote the iid error terms. $d_{max}$ denotes the highest order of integration of the variables.
From Eq. (1), $x_t$ causes $y_t$ if $\varphi_{1i} \neq 0, \forall i = 1, 2, ..., m$. In a similar vein, in Eq. (2), $y_t$ causes $x_t$ if $\delta_{1i} \neq 0, \forall i = 1, 2, ..., m$. The associated test statistic of these hypotheses is *chi-squared* distributed. Suppose that $\delta_{1i} = 0, \forall i = 1, 2, ..., m$, and let $\delta = vec(\delta_1, \delta_2, ..., \delta_m)$ denote a vector of $m$ VAR coefficients. According to Toda and Yamamoto (1995), for a suitably selected $Z$, the modified *Wald*-statistic for this hypothesis takes the form

$$W = T(\delta'Z'(Z\hat{\Sigma}_uZ')^{-1}Z\delta)$$

(3)

where $\delta$ is the OLS estimate of $\delta$; $\hat{\Sigma}_u$ denotes a consistent estimate of the variance-covariance matrix of $\sqrt{T}(\delta - \delta)$; $T$ denotes the sample size. $W$, which is the test statistic, is *chi-squared* distributed with $m$ degrees of freedom.

4.3 Data

The period covered in this paper is from 1990 to 2014. The data are obtained from the World Bank’s Global Financial Development Database (2016) and World Development Indicators (2016). These databases are preferred because they are very reliable and have been used by previous studies. The variables employed in this paper are: (i) economic growth, measured by the annual percentage change in real GDP per capita (constant 2005 US$); (ii) bank-based financial development, measured by two proxies, namely: private credit by deposit money banks as a percentage of GDP ($PC/GDP$), and bank deposits as a percentage of GDP ($BD/GDP$), and (iii) inflation, measured by annual percentage change in consumer prices.

5. Empirical Results

5.1 Results of Stationarity Tests

Before assessing the causal nexus between bank-based financial development and economic growth in Hong Kong, we first establish the stationarity properties of the variables. This step is necessary in order to establish the additional lag(s) (i.e. $d_{max}$) to be included in the augmented VAR model – which will be used to test for causality following Toda and Yamamoto (1995). In this paper, we utilise the ADF and DF-GLS tests and then we undertake the stationarity analysis by taking into account the no trend and trend options. Table 2 shows the results of the stationarity tests of the variables in their levels and first differences. The variables are stationary after first difference at the conventional levels of significance (see Table 2). Hence the additional lag(s) to be included in the augmented VAR model is 1 (i.e. $d_{max} = 1$).

**First Difference – ADF Test**

\[
\begin{array}{ccc}
\Delta \text{lnGDP} & -4.096*** & -4.006** \\
\Delta \text{INF} & -4.367*** & -4.769*** \\
\Delta \text{lnPC/GDP} & -2.812* & -2.903* \\
\Delta \text{lnBD/GDP} & -4.689*** & -4.661*** \\
\end{array}
\]

**First Difference – DF-GLS Test**

\[
\begin{array}{ccc}
\Delta \text{lnGDP} & -4.116*** & -4.153*** \\
\Delta \text{INF} & -4.325*** & -4.810*** \\
\Delta \text{lnPC/GDP} & -2.534** & -2.965* \\
\Delta \text{lnBD/GDP} & -3.281*** & -3.378*** \\
\end{array}
\]

**Notes:**

1) *, ** and *** denote, respectively, 10%, 5% and 1% significance levels.
2) The critical values for the Dickey-Fuller GLS test are based on Table 1 of Elliot et al. (1996).
3) \(\Delta\) denotes first difference operator.
4) lnGDP = natural log of real GDP per capita, lnPC/GDP = natural log of private credit by deposit money banks as a percentage of GDP, lnBD/GDP = natural log of bank deposits as a percentage of GDP, and INF = inflation.

## 5.2 Lag Selection, Model Diagnostics, and the Results for Causality Testing

It is important to select the appropriate lag length when performing the Toda-Yamamoto test. Here, our selection of the optimal lag length is based on the Akaike Information Criterion (AIC), the Hannan-Quinn Criterion (HQC), the Schwartz Information Criterion (SIC), and the Final Prediction Error (FPE). The optimal lag selected in our analysis is 3 (see Tables 3 and 4). Hence, we specify the two VAR models based on 3 lags. Apart from selecting the optimal lags, the best models should be free of serial correlation and be structurally stable (see Ho and Iyke, 2016). We therefore test for structural stability and serial correlation. These results are presented in Tables 3 and 4. The inverses of the roots of the characteristic equations are above one in all the cases (see Tables 3 and 4), indicating that the models are structurally stable. This is supported by Figures A.1, and A.2, which show the cumulative sum of recursive residual plots. The models are also free of serial correlation. This evidence is shown, respectively, by the chi-squared statistic of 89.739 with a p-value of 0.971 for the lnGDP, INF and lnPC/GDP model; and 91.110 and 0.963 for the lnGDP, INF and lnBD/GDP model.

Note: NA denotes non-applicable.

Having satisfied all the requirements underlying the Toda-Yamamoto test, we estimate a \( VAR(4) \) for each of the two models (i.e. \( m = 3 \) and \( d_{max} = 1 \)). Table 3 shows the causality tests between \( \ln \)GDP and \( \ln \)PC/GDP. From Table 3, it is evident that there is a unidirectional causal flow running from \( \ln \)PC/GDP to \( \ln \)GDP at 5% level of significance, as indicated by the \( chi\)-squared statistic of 10.000, with corresponding \( p\)-value of 0.019, for the \( \ln \)GDP equation. Similarly, there is a unidirectional causal flow running from \( \ln \)BD/GDP to \( \ln \)GDP at 5% level of significance, as indicated by the \( chi\)-squared statistic of 10.700, with corresponding \( p\)-value of 0.013, for the \( \ln \)GDP equation (see Table 4). From these results, bank-based financial development is a precursor to economic growth in Hong Kong. In other words, Hong Kong tends to follow the supply-leading hypothesis. This finding is consistent with the existing findings such as those of Phiri (2015), Sehrawat and Giri (2015), Menyah et al. (2014), Hsueh et al. (2013), and Bittencourt (2012). The finding implies that policymakers in Hong Kong are able to drive economic growth using bank-based financial development as a tool. Hence, one way Hong Kong can continue to sustain its tremendous advancement is to ensure that its banking system is functioning efficiently. Robust stabilizers should be built to make the banking system insusceptible to systemic and external shocks.

### 6. Conclusion

This paper assessed the causal nexus between bank-based financial development and economic growth in Hong Kong. It answered the following question: Does Hong Kong follows a supply-leading or a demand-following hypothesis? Hong Kong is a typical economy which has experienced both bank-based financial expansion and economic expansion in the last three decades. It therefore serves as a quintessence for testing this overarching debate. Many deficiencies exist in the majority of the previous studies, including the use of limited data for methods that are inefficient in small samples, and problems of variable omission bias. This paper avoided those problems by using the Toda-Yamamoto test for causality, and by introducing inflation as a conduit between bank-based financial development and economic growth. The paper is also among a few to assess the above-mentioned question in the case of Hong Kong. Using a dataset that covered the period 1990 – 2014, and two indicators of bank-based financial development, the paper found
Hong Kong to follow the supply-leading hypothesis. This implied that the banking sector has been an important driver of economic growth in Hong Kong during the study period. Policymakers in this economy will only enhance economic growth further by targeting and ensuring efficient performance of bank-based financial institutions.
