Email: nyonithabani35@gmail.com

Abstract

Of uttermost importance is the fact that forecasting macroeconomic variables provides a clear picture of what the state of the economy will be in future (Sultana et al, 2013). Nothing is more important to the conduct of monetary policy than understanding and predicting inflation (Kohn, 2005). Inflation is the scourge of the modern economy and is feared by central bankers globally and forces the execution of unpopular monetary policies. Inflation usually makes some people unfairly rich and impoverishes others and therefore it is an economic pathology that stands in the way of any sustainable economic growth and development. Models that make use of GARCH, as highlighted by Ruzgar & Kale (2007); vary from predicting the spread of toxic gases in the atmosphere to simulating neural activity but Financial Econometrics remains the leading discipline and apparently dominates the research on GARCH. The main objective of this study is to model monthly inflation rate volatility in Zimbabwe over the period July 2009 to July 2018. Our diagnostic tests indicate that our sample has the characteristics of financial time series and therefore, we can employ a GARCH – type model to model and forecast conditional volatility. The results of the study indicate that the estimated model, the AR (1) – GARCH (1, 1) model; is indeed an AR (1) – IGARCH (1, 1) process and is not only appropriate but also the best. Since the study provides evidence of volatility persistence for Zimbabwe’s monthly inflation data; monetary authorities ought to take into cognisance the IGARCH behavioral phenomenon of monthly inflation rates in order to design an appropriate monetary policy.

Key Words: ARCH, Forecasting, GARCH, IGARCH, Inflation Rate Volatility, Zimbabwe.

1. Introduction

Although being slightly perceptible, inflation is one of the most difficult to define and bound complex phenomena (Baciu, 2015). Inflation can be defined as the persistent and continuous rise in the general prices of commodities in an economy (Nyoni & Bonga, 2018a). Inflation is the persistent increase in the general price level within the economy which affects the value of the domestic currency (Fatukasi, 2012). Maintenance of price stability continues to be one of the main objectives of monetary policy for most countries in the world today (Nyoni & Bonga, 2018a) and Zimbabwe is not an exception. Sound and productive level of inflation, as noted by Idris & Bakar (2017); is certainly regarded as a repercussion of fiscal prudence and essential criteria for the attainment of a sustainable level of growth and development. Owing to the fact that the effect of monetary policy has a time lag, as already noted by Bokil & Schimmelpfennig (2005); policy makers inevitably require frequent updates to the path of inflation. Policy makers can get prior indication about possible future inflation through inflation forecasting. In this study we use the GARCH approach to model monthly inflation rate volatility in Zimbabwe.
Accomplishment of price stability, in the sense of a low and steady inflation, is key to economic growth and it is one of the objectives of almost every central bank throughout the world (Iqbal & Sial, 2016). Currently, policy makers in Zimbabwe are facing the twin challenge of maintaining price stability while stimulating economic growth. Achieving these two goals simultaneously is by no means easy. Just like other developing nations, Zimbabwe’s main macroeconomic targets are generally three-fold, namely; a growth target to support higher employment and poverty alleviation; an inflation target to maintain internal economic stability; and a target for stability of the Balance of Payments (BoP). Therefore, Zimbabwe generally needs a combination of three policy instruments, namely; monetary policy, fiscal policy and policies for managing the BoP; in order to achieve her macroeconomic targets. In attempting to model and forecast monthly inflation rate, this study will give birth to policy prescriptions that are envisaged to assist policy makers in properly coordinating Zimbabwe’s macroeconomic targets in a sustainable manner.

A number researchers have analyzed inflation in Zimbabwe, for example; Chhibber et al (1989), Dzvanga (1995), Sunde (1997), Makochekanwa (2007), Pindiriri & Nhavira (2011), Pindiriri (2012), Kavila & Roux (2015), Mpofo (2017) and Kavila & Roux (2017) but no study has attempted to employ the GARCH approach to modeling and forecasting inflation in Zimbabwe, hence the need for this study. The rest of the paper is organized as follows: literature review; materials & methods; results: presentation, interpretation & discussion; and conclusion & recommendations; in chronological order.

2. Literature Review

Theoretical Literature Review

The Monetarist Theory of Inflation
The monetarist school of thought, also known as the modern Quantity Theory of Money (QTM); argues that inflation is always and everywhere a monetary phenomenon which comes from rapid expansion in the quantity of money than in the expansion in the quantity of output (Nyoni & Bonga, 2018a). Hinged on the QTM, monetarists believe that the quantity of money is the main determinant of the price level. In their diagnosis of the QTM, monetarists finalize that any change in the quantity of money affects only the price level, leaving the real sector of the economy totally unaffected.

The Keynesian Theory of Inflation
Money creation does not have a direct impact on aggregate demand but rather through interest rates, which themselves have a minimal impact on aggregate demand (Samuelson, 1971). Keynesians strictly disputed the monetarist view that the velocity of circulation of money is stable; instead, arguing that it is rather unstable. The monetarist view on policy rules was criticized by Modigliani (1977), who advocated for the use of stabilization policies dealing with inflation. Keynesians also rejected the monetarist notion that markets are able to adjust freely to disruptions and return to full employment level of output.

The Neo – Keynesian Theory of Inflation
Based in the Keynesian school of thought, the Neo – Keynesian Theory of Inflation states that there are three types of inflation; namely demand pull, cost – push and structural inflation. Demand pull inflation occurs when aggregate demand exceeds available supply. Cost – push inflation occurs due to sudden decrease in aggregate supply. Structural inflation basically occurs as a result of (structural) changes in monetary policy in the country.

Demand Pull Inflation
Demand pull theorists agree that the primary cause of inflation is the persistent increase in the aggregate demand for goods against a relatively fixed supply of goods (Addison & Burton, 1979). The source of inflation emanates from changes to the demand side of the aggregate goods market. An increase in aggregate demand without a corresponding increase in supply, results in an inflationary gap which induces increase in prices (Kavila & Roux, 2017). Inflation is generated by the pressures of excess demand as it approaches and exceeds the full employment level of output (Keynes, 1936; Smithies, 1942). If the economy is operating at full employment output and aggregate demand rises, the output level cannot respond automatically because of full employment constraints. Consequently, the only way to clear the goods market is by raising the money prices for goods. The proponents of demand pull inflation argue that the inflationary gap in the goods market results from a disequilibrium in the money market (Kavila & Roux, 2017). Therefore, inflation is caused by an expansionary monetary policy (Friedman, 1956), where the rate of expansion in the quantity of money is more than the rate of increase in output (Kavila & Roux, 2017).

**Cost – push Inflation**

Cost push theories of inflation cite non – monetary supply – oriented influences that raise costs and hence prices (Kavila & Roux, 2017). While recognizing the significance of monetary expansion as a source of inflation, proponents of cost push theory view monetary growth as playing the accommodating or passive role (Humphrey, 1977). Cost inflation theories emphasize the increase of production costs instead of excess aggregate demand (Kavila & Roux, 2017).

**Structural Inflation**

Structuralist models of inflation emphasize on supply – side factors as determinants of inflation (Bernanke, 2005). Structuralism generally argues that there are factors unique to a country’s institutional dynamics that define a country’s predisposition to inflation. The structuralist ideology attributes inflation to bottlenecks in the economy and such bottlenecks include inelastic supply, monopoly tendencies and labor inflexibility amongst others. Food prices, administered prices, wages and import prices, as noted by Khan & Schimmelpfennig (2006); are also considered as sources of inflation. Structuralists argue that the world is inflexible to such an extent that the price mechanism tends to fail to help the market achieve equilibrium.

**Expectations Theory of Inflation**

Inflation expectations are perceptions or views of economic agents about future inflation trends (Mohanty, 2012). Inflation expectations are a basic building block in today’s macroeconomic theory and monetary policy (Gali, 2008; Sims, 2009). The ability of central banks to achieve price stability is greatly influenced by economic agents’ inflation expectations and in this regard, the management of the perceptions is a critical component in the enhancement of price stability (Bomfin & Rodenbusch, 2000; Loleyt & Gurov, 2010).

Expectations can be formed either adaptively or rationally. Adaptive expectations exist when economic agents form their expectations based on past and current experience with inflation. Owing to their backward looking approach, adaptive expectations have attracted a lot of criticisms, giving birth to the rational expectations theory. Rational expectations, as noted by Mohanty (2012); are formed when economic agents take into account all the available
information about inflation and then factor in the central bank’s monetary policy reaction function. The Phillips curve relationship, as already highlighted by Elbers & Steinbach (2007); is now expectations augmented, further signifying the importance of expectations in macroeconomic policy.

As suggested by various theories of inflation (discussed here), indeed causes of inflation differ, of course according to school of thought. While economic thinking on the nature and effect of inflation may differ, we cannot rule out the existence of a consensus on the need to control the inflation process. Unfortunately, in Zimbabwe; monetary authorities have a well – known history of gross macroeconomic mismanagement.

**Empirical Literature Review**

As shown in table 1 above, no relevant study has been done in the context of Zimbabwe so far. Hence, this study is the first of its kind.
3. Materials & Methods

Model Building & Estimation Procedures

Autoregressive Conditionally Heteroskedastic (ARCH) model

A typical structural model can be expressed as follows:

\[ w_t = \theta_0 + \theta_1 z_{1t} + \theta_2 z_{2t} + \theta_3 z_{3t} + \theta_4 z_{4t} + \varepsilon_t \]  \[1\]

where \( \theta_0 \) is the model constant, \( \theta_1 - \theta_4 \) are estimation parameters, \( z_{1t} - z_{4t} \) are explanatory variables, \( w_t \) is the dependent variable and \( \varepsilon_t \) is the white noise error term.

or more compactly as:

\[ w_t = Z\theta + \varepsilon_t \]  \[2\]

with \( \varepsilon_t \approx N (0, \sigma_t^2) \)

where \( Z \) and \( \theta \) are vectors of explanatory variables and estimation parameters respectively.

As usual, homoskedasticity is assumed; that is:

\[ \text{var} (\varepsilon_t) = \sigma_t^2 \]  \[3\]

If equation \[3\] above is not true, then that would be known as heteroskedasticity and this would imply that standard error estimates are misleading. In financial time series, however; it is rare that the variance of the errors will be constant over time, and therefore it is reasonable to take into account a model that does not assume that the variance is constant and yet describes how the variance of the errors evolves; and such a model is an ARCH model. To explain the mechanics behind the ARCH model, we begin by operationally defining the conditional variance of a random variable, \( \varepsilon_t \):

\[ \sigma_t^2 = \text{var}(\varepsilon_t|\varepsilon_{t-1}, \varepsilon_{t-2}, ...) = E[\varepsilon_t^2|\varepsilon_{t-1}, \varepsilon_{t-2}, ...] \]  \[4\]

assuming that:

\[ E(\varepsilon_t) = 0 \]  \[5\]

such that:

\[ \sigma_t^2 = \text{var}(\varepsilon_t|\varepsilon_{t-1}, \varepsilon_{t-2}, ...) = E[\varepsilon_t^2|\varepsilon_{t-1}, \varepsilon_{t-2}, ...] \]  \[6\]

Equation \[6\] above simply avers that the conditional variance of a zero mean normally distributed random variable \( \varepsilon_t \) is equal to the conditional expected value of the square of \( \varepsilon_t \). The equation below:

\[ \sigma_t^2 = \varphi_0 + \varphi_1 \varepsilon_{t-1}^2 \]  \[7\]

is known as an ARCH(1) model simply because the conditional variance depends only on one lagged squared error. Equation \[7\] is not a complete model because so far we have not mentioned anything about the conditional mean; which describes how the dependent variable, \( w_t \);
varies over time. There is no rule of thumb on how to specify the conditional mean equation; therefore it can take apparently any form that the researcher wishes. By combining equations [1] and [7], we can show that a typical full model looks like equations [8] and [9] below:

\[ w_t = \theta_0 + \theta_1 z_{1t} + \theta_2 z_{2t} + \theta_3 z_{3t} + \theta_4 z_{4t} + \epsilon_t; \epsilon_t \sim N(0, \sigma_t^2) \]  
\[ \sigma_t^2 = \phi_0 + \phi_1 \epsilon_{t-1}^2 \]  

The model given by equations [8] and [9] can be generalized to a case where the error variance depends on p lags of squared errors, which is operationally defined as an ARCH (p) model:

\[ \sigma_t^2 = \phi_0 + \phi_1 \epsilon_{t-1}^2 + \ldots + \phi_p \epsilon_{t-p}^2 \]  

**Generalized ARCH (GARCH)**  

The equation below:

\[ \sigma_t^2 = \phi_0 + \phi_1 \epsilon_{t-1}^2 + \phi_1 \sigma_{t-1}^2 \]  

is the simplest but often very useful case of a GARCH process, the GARCH(1,1) model; where \( \sigma_t^2 \) is the conditional variance, \( \phi_0 \) is the constant, \( \phi_1 \epsilon_{t-1}^2 \) is the information about the volatility during the previous period, and \( \phi_1 \sigma_{t-1}^2 \) is the fitted variance from the model during the previous period. A GARCH model can be expressed as an ARMA process of squared residuals. For instance, given equation [11] above, we know that:

\[ E_{t-1}[\epsilon_t^2] = \sigma_t^2 \]  

such that:

\[ \epsilon_t^2 = \phi_0 + (\phi_1 + \phi_1) \epsilon_{t-1}^2 + \mu_t - \phi_1 \mu_{t-1}^2 \]  

which is an ARMA (1, 1) process. Here:

\[ \mu_t = \epsilon_t^2 - E_{t-1}[\epsilon_t^2] \]  

is the white noise error term. Given the ARMA representation of the GARCH model, we can conclude that stationarity of the GARCH (1, 1) model requires:

\[ \phi_1 + \phi_1 < 1 \]  

Taking the unconditional expectation of equation [11], we get:

\[ \sigma_t^2 = \phi_0 + \phi_1 \sigma_{t-1}^2 + \phi_1 \sigma_{t-1}^2 \]  

so that:

1 GARCH models are better than ARCH models because they are more parsimonious and thus they subsequently deal with the problem of over-fitting.

ARCH and GARCH models have emerged as the most prominent tools for estimating volatility, because they are adequate to capture the random movement of the financial data series (Anton, 2012). The basic and most widespread model is GARCH (1, 1) (Ruzgar & Kale, 2007). ARCH models were developed by Engle (1982). GARCH models were developed independently by Bollerslev (1986) and Taylor (1986).
\[ \sigma^2 = \frac{g}{\mathcal{H}} \] \[ \text{[17]} \]

where \( g = \phi_0 \) and \( \mathcal{H} = 1 - \phi_1 \). For this unconditional variance to exist, then the (inequality) equation [15] must hold water and for it to be positive, then:

\[ g > 0 \] \[ \text{[18]} \]

Equation [11] above can be generalized to a case where the current conditional variance is parameterized to depend upon \( p \) lags of the squared error and \( q \) lags of the conditional variance, which is operationally defined as a GARCH\((p, q)\) model; as shown below:

\[ \sigma_t^2 = \phi_0 + \phi_1 \epsilon_{t-1}^2 + \ldots + \phi_p \epsilon_{t-p}^2 + \phi_1 \sigma_{t-1}^2 + \ldots + \phi_q \sigma_{t-q}^2 \] \[ \text{[19]} \]

Equation [19] can also be expressed as follows:

\[ \sigma_t^2 = \phi(t) \epsilon_t^2 + \phi(t) \sigma_t^2 \] \[ \text{[20]} \]

where \( \phi(t) \) and \( \phi(t) \) denote the AR and MA polynomials respectively, with:

\[ \phi(t) = \phi_1 + \ldots + \phi_p t \] \[ \text{[21]} \]

and:

\[ \phi(t) = \phi_1 t + \ldots + \phi_q t^q \] \[ \text{[22]} \]

or as:

\[ \sigma_t^2 = \phi_0 + \sum_{i=1}^{p} \phi_i \epsilon_{t-i}^2 + \sum_{j=1}^{q} \phi_j \sigma_{t-j}^2 \] \[ \text{[23]} \]

where condition [15], is now generalized as:

\[ \sum_{i=1}^{p} \phi_i + \sum_{j=1}^{q} \phi_j < 1 \] \[ \text{[24]} \]

If all the roots of the polynomial:

\[ 1 - \phi(t) t^{-1} = 0 \] \[ \text{[25]} \]

lie outside of the unit circle, we get:

\[ \sigma_t^2 = \phi_0 (1 - \phi(t) t^{-1} + \phi(t) t^{-1} \epsilon_t^2) \] \[ \text{[26]} \]

which may be regarded as an ARCH\((\infty)\) process, just because the conditional variance linearly depends on all previous squared residuals. The unconditional variance is then given by:

\[ \sigma^2 = E(\epsilon_t^2) = \phi_0 (1 - \sum_{i=1}^{p} \phi_i + \sum_{j=1}^{q} \phi_j) \] \[ \text{[27]} \]

Obviously, the unconditional variance will be infinite if:

\[ \phi_1 + \ldots + \phi_p + \phi_1 + \ldots + \phi_q = 1 \] \[ \text{[28]} \]

\(^2\) where \( t \) is the lag operator.
In many financial time series, conditions [15] and [24]; whose implication is basically the same, are close to unity; indicating persistent volatility. In the event that:

\[ \phi_1 + \phi_1 = 1 \] \[ \text{[29]} \]

or more generally:

\[ \sum_{i=1}^{p} \phi_i + \sum_{j=1}^{q} \phi_j = 1 \] \[ \text{[30]} \]

or equally rewritten:

\[ \phi(t) + \phi(t) = 1 \] \[ \text{[31]} \]

then the resulting process is not covariance stationary\(^3\) and is technically referred to as an Integrated GARCH or IGARCH, implying that current information remains vital when forecasting the volatility for all horizons. However, Nelson (1990) argues that although GARCH (or IGARCH) model is not covariance stationary, it is strictly stationary or ergodic and the standard asymptotically based inference procedures are generally valid. In the IGARCH model, as noted by Anton (2012); any shock to volatility is permanent and the unconditional variance is infinite.

**Model Selection Criteria (Goodness – of – fit Measure)**

The model selection criterion used in most studies is usually based either on all or one of the following:

\[ \text{AIC} = -2 \log (L) + 2(m) \] \[ \text{[32]} \]

\[ \text{BIC} = -2 \log (L) + m \log n \] \[ \text{[33]} \]

\[ \text{HQ} = -2 \log (L) + 2m \log (\log n) \] \[ \text{[34]} \]

\[ \text{SIC} = -2 \log (L) + (m + m \log n) \] \[ \text{[35]} \]

where AIC is the Akaike Information Criterion, BIC is the Bayesian Information Criterion, HQ is the Hannan – Quinn Criterion, SIC is the Shwarz Information Criterion, \(n\) is the sample size, \(m\) is the number of parameters in the model and \(\log (L)\) is the loglikelihood. The optimal model (the one that strikes a balance between goodness of – fit and parsimony) is usually the one that minimizes these criteria. In this study we take into consideration all of the above criteria, except the BIC.

**Table 2**

<table>
<thead>
<tr>
<th>Model</th>

</tr>
<tr>
<td>ii GARCH (2, 1) AR (1)</td>
<td>211.0228</td>
<td>218.5793</td>
<td>229.6668</td>
</tr>
</tbody>
</table>

\(^3\) Covariance stationarity is the condition that is more frequently assumed in GARCH models. It does require that all first and second moments exist whereas strict stationarity does not. In this one respect, covariance stationarity is a stronger condition (Holton, 1996).
Table 2 above shows that model [ii] is the one with the lowest AIC, HQC and SIC values. In general, the model with the lowest selection criterion values is usually taken as the optimal model. However, in this study we decide (the other way round) to consider model [i]; the reason being that of the need to specify the most parsimonious model while also ensuring that the chosen model is the best in terms of both in-sample and out-of-sample forecasts, as confirmed by forecast evaluation statistics shown in table 3 below. Model [i] is the most parsimonious model and has a better forecast accuracy (as shown in table 3 below), therefore it is preferred. According to Brooks (2008), a GARCH (1, 1) model will be sufficient to capture the volatility clustering in the data, and rarely is any higher order model estimated or even entertained in the academic finance literature. In the same line of thought, Hansen & Lunde (2005) argue that there is no evidence that a GARCH (1, 1) model is outperformed by any other model/s. Model [i] is the appropriate model since it strikes a balance amongst goodness-of-fit, parsimony and forecast performance. Table 3 below also further justifies our decision to choose model [i].

Forecast Evaluation (Forecasting Performance Measure)

The forecast evaluation statistics shown in table 2 below were computed as follows:

\[
\text{MSE} = \frac{1}{T} \sum_{t=1}^{T} (r_t^2 - \sigma_t^2)^2 \tag{36}
\]

\[
\text{MAE} = \frac{1}{T} \sum_{t=1}^{T} |r_t^2 - \sigma_t^2| \tag{37}
\]

\[
\text{RMSE} = \sqrt{\text{MSE}} \tag{38}
\]

where \(r_t^2\) is used as a substitute for the realized or actual variance, \(\sigma_t^2\) is the forecasted variance, and \(T\) is the number of observations in the simulations of the sample.

<table>
<thead>
<tr>
<th>Model</th>
<th>Mean Squared Error (MSE)</th>
<th>Root Mean Squared Error (RMSE)</th>
<th>Mean Absolute Error (MAE)</th>
</tr>
</thead>
<tbody>
<tr>
<td>i</td>
<td>GARCH (1, 1) AR (1)</td>
<td>1.2159</td>
<td>1.1027</td>
</tr>
<tr>
<td>ii</td>
<td>GARCH (2, 1) AR (1)</td>
<td>1.2556</td>
<td>1.1205</td>
</tr>
</tbody>
</table>

Smaller values of the forecast evaluation statistics generally indicate that the forecast is quite good. As shown in table 3 above, model [i], as compared to model [ii]; is the one with the lowest forecast evaluation statistics, hence it is quite better in terms of forecast performance.

Model Specification

The appropriate equations for the mean and variance were specified as follows:

In practice a GARCH (1, 1) specification often performs very well (Verbeek, 2004) and thus, as noted by Wang (2009); in empirical applications a GARCH (1, 1) model is widely adopted. In the same line of thought, Kozhan (2010); notes that the most commonly used model is a GARCH (1, 1) model with only three parameters in the conditional variance equation. Usually a GARCH (1, 1) model with only three parameters in the conditional variance equation is adequate to obtain a good model fit for time series (Zivot, 2008).

The best forecasting value is evaluated from the mean squared error (Dritsaki, 2018).

4 In practice a GARCH (1, 1) specification often performs very well (Verbeek, 2004) and thus, as noted by Wang (2009); in empirical applications a GARCH (1, 1) model is widely adopted. In the same line of thought, Kozhan (2010); notes that the most commonly used model is a GARCH (1, 1) model with only three parameters in the conditional variance equation.

5 The best forecasting value is evaluated from the mean squared error (Dritsaki, 2018).
AR (1)⁶ – GARCH (1, 1) model⁷, econometrically presented as follows:

\[
\text{INF}_t = \lambda_0 + \lambda_1 \text{INF}_{t-1} + \epsilon_t; \quad \epsilon_t \approx N(0, \sigma_t^2) \] …………………………………………………………….. [39]

\[
\sigma_t^2 = \delta + \alpha_1 \epsilon_{t-1}^2 + \beta_1 \sigma_{t-1}^2 \] ……………………………………………………………………….. [40]

where:

\[
\delta \geq 0
\]

\[
\alpha_1 \geq 0
\]

\[
\beta_1 \geq 0 \] …………………………………………………………………………………….. [41]

where equation [39] is the mean equation, equation [40] is the variance equation; \( \lambda_0 \) is the constant (in the mean equation), \( \lambda_1 \) is the estimation parameter (in the mean equation), \( \text{INF}_t \) is monthly inflation rate at time \( t \), \( \text{INF}_{t-1} \) is previous period monthly inflation rate; \( \delta \) is the constant (in the variance equation), \( \alpha_1 \) & \( \beta_1 \) are estimation parameters (in the variance equation); everything else remains as previously defined above.

Data Collection

All the data used in this study was collected from Zimbabwe Statistics Agency (ZimStats).

Diagnostic Tests

Testing for Stationarity

The ADF⁸ test

The monthly inflation rate series was tested for stationarity using the Augmented – Dickey Fuller (ADF) unit root test as follows:

\[
\Delta \text{INF}_t = b_0 + \sum b_j \Delta \text{INF}_{t-j} + \beta \text{INF}_{t-1} + \mu_t \] …………………………………………………………………………………………….. [42]

Where \( \Delta \) is the difference operator, \( b_0 \) is the drift parameter, \( \beta \) is the coefficient on a time trend, \( \mu_t \) is the error term, and \( \text{INF}_t \) is monthly inflation at time \( t \).

The null hypotheses of no unit root tests are:

H₀: \( \beta=\gamma=0 \) (if there is a trend \( [F – test] \)) and H₀: \( \gamma=0 \) (if there is no trend \( [t – test] \)). If the null hypothesis is rejected, like in this case; the data are stationary and can be used without differencing and if the null hypothesis is accepted, there is a unit root; therefore we ought to difference the data. Since the probability (p) value was found to be equal to 0.0006835, the null hypothesis was rejected at 1% level of significance and therefore the series is stationary.

Testing for ARCH effects

⁶ The intrinsic nature of a time series is that successive observations are dependent or correlated (Faisal, 2012) and therefore, we specify an AR (1) process for the mean equation.

⁷ Based on the selection criteria in table 1 and forecast evaluation statistics in table 2 below.

⁸ The model may be run without \( t \) if a time trend is not necessary (Salvatore & Reagle, 2002).
The Lagrange Multiplier (LM) Test

Run the mean equation or any postulated linear regression of the form given [in equation one above]; for example:

\[ Y_t = \gamma_0 + \gamma_1 \Omega_{1t} + \gamma_2 \Omega_{2t} + \gamma_3 \Omega_{3t} + \gamma_4 \Omega_{4t} + z_t \]  

Where \( Y_t \) is the dependent variable, \( \gamma_0 \) – \( \gamma_4 \) are estimation parameters of the mean equation, \( \Omega_{1t} \) - \( \Omega_{4t} \) are explanatory variables and \( z_t \) is the disturbance term. Save the residuals, \( \hat{z}_t \). Square the residuals and regress them on \( p \) own lags to test for ARCH of order \( p \), that is; run the regression:

\[ \hat{z}_t^2 = \gamma_0 + \gamma_1 \hat{z}_{t-1}^2 + \ldots + \gamma_p \hat{z}_{t-p}^2 + \nu_t \]  

where \( \nu_t \) is an error term. Obtain \( R^2 \) from this regression. The test statistic, defined as \( TR^2 \) (the number of observations multiplied by the coefficient of multiple correlation); is distributed as a \( \chi^2(p) \). The null and alternative hypotheses are:

\( H_0: \gamma_1 = 0 \) and \( \gamma_2 = 0 \) and \( \gamma_3 = 0 \) and \( \ldots \) and \( \gamma_p = 0 \)

\( H_1: \gamma_1 \neq 0 \) or \( \gamma_2 \neq 0 \) or \( \gamma_3 \neq 0 \) or \( \gamma_p \neq 0 \)

In this study, the ARCH / GARCH effects test described above was done and the results are shown below:

Chi – square (2) = 105.663 [0.0000000000000000000000113622]

The results of the test above indicate that there are (G) ARCH effects in the chosen (optimal) model, since the \( p \) – value [which is approximately equal to zero] is significant at 1% level of significance and therefore it is appropriate to estimate a GARCH model.

4. Results: Presentation, Interpretation & Discussion

Descriptive Statistics

<table>
<thead>
<tr>

</tr>
<tr>
<td>Skewness</td>
<td>-0.61431</td>
</tr>
<tr>
<td>Excess Kurtosis</td>
<td>1.2829</td>
</tr>
</tbody>
</table>

As shown in the table above, the mean is positive but is not close to zero as anticipated. The difference between the maximum and minimum is 13% and this indicates that there are generally no outliers in the data since this difference is generally small and quite reasonable for our data set. The skewness coefficient is negative as shown, implying that our time series has a long left tail and is non – symmetric. The rule of thumb for kurtosis, according to Nyoni & Bonga (2017h); is that it should be around 3 for normally distributed variables. As shown in the table
above, excess kurtosis is equal to 1.2829, implying that our variable (monthly inflation rate) is not normally distributed.

</tbody>
</table>

The model tabulated above can be presented as follows:

\[
\text{INF}_t = 0.04 + 0.98 \text{INF}_{t-1} \] .......................... ........................................................... [45]

\[
p: (0.421) (0.000) \\
S.E: (0.054) (0.023)
\]

\[
\sigma_t^2 = 0.04 + 0.58 \varepsilon_{t-1}^2 + 0.48 \sigma_{t-1}^2 \] .......................... ........................................................... [46]

\[
p: (0.049) (0000) (0000) \\
S.E: (0.019) (0.11) (0.99)
\]

**Interpretation & Discussion of Results**

The estimated model is acceptable simply because the necessary and sufficient conditions (specified in [41]) have been met. As theoretically expected, the parameters \( \lambda_0 \) and \( \alpha_1 \) are greater than zero (0) and \( \beta_1 \) is positive to ensure that the conditional variance \( \sigma_t^2 \) is non–negative and therefore the positivity constraint of the GARCH model is not violated. Thus the estimated GARCH (1, 1) model seems quite good for explaining the behavior of monthly inflation rate volatility in Zimbabwe. Both \( \alpha_1 \) and \( \beta_1 \) are positive and statistically significant at 1% level of significance. \( \alpha_1 \) is positive and statistically significant, indicating that strong GARCH effects are apparent. In fact a 1% increase in previous period volatility leads to an approximately 0.58% increase in current volatility of monthly inflation. \( \beta_1 \) is positive & significant and less than one, indicating that the impact of old news on volatility is significant. In fact an increase of 1% in previous period variance will lead to approximately 0.42% increase in current volatility of monthly inflation rate. Since\(^{10}\):

\[
\alpha_1 + \beta_1 = 1 \] .......................... ........................................................... [47]

---

\(^9\) The *, ** and *** means significant at 10%, 5% and 1% levels of significance; respectively. 
\(^{10}\) \( \alpha_1 \) & \( \beta_1 \) are as defined previously.
it confirms that the estimated GARCH model is not covariance stationary but rather ergodic or strictly stationary. The estimated model can thus be referred to as an IGARCH (1, 1) process. This implies that persistent variance is not inexistent and volatility shocks have a permanent effect and therefore current information remains critical for the forecasts of the conditional variances for all horizons. Caporale et al. (2003) noted that the high estimated volatility persistence obtained using GARCH models might be attributed to structural changes in the variance process. Tsay (2002) highlights the fact that the actual cause of persistence deserves a careful investigation. Our results are similar to previous studies such as Moroke & Luthuli (2015) whose AR (1) – IGARCH (1, 1) model suggested a high degree of persistence in the conditional volatility of the inflation series in South Africa.

The above table is a summary of the forecasting results of monthly inflation rate over the period August 2018 – August 2020.

**Predicted monthly inflation rates over the period August 2018 – August 2020**
The graph above shows that monthly inflation rate in Zimbabwe is generally on a downward trend over the next 2 years (or even beyond); as long as economic conditions seldom fluctuate much. The downward trend can be attributed to the adoption of the United States Dollar in February 2009, just after Zimbabwe had reached the climax of the 2008 hyper-inflationary era. The graph indicates that by December 2018, inflation will be approximately 4.14% and by June 2019, inflation will be somewhere around 3.95%. This downward spiral is expected to continue into the future, especially given the fact that there are no plans to reintroduce the Zimbabwean dollar. Inflation that ranges from 0% - 10% or simply one digit figure, according to Nyoni & Bonga (2018a); is beneficial for economic growth and this is true because such low inflation rate ensure price stability, which is one of the most crucial objectives of monetary policy. This reasoning is in line with many researchers such as Hasanov (2010) and Marbuah (2010) who assert that inflation that is less than 9% or generally low (single-digit inflation) is generally beneficial to economic growth. Low or moderate inflation as noted by Hossin (2015); is an indicator of macroeconomic stability and creates an environment conducive for investment. Nyoni & Bonga (2017) emphasize that lower rates of inflation currently obtaining in Zimbabwe

are favorable. However, as already warned by Nyoni & Bonga (2018a); policy makers need to be aware of too low inflation (i.e. inflation that is lower than 0% or in the negative territory).

5. Conclusion & Recommendations

Monetary policy is more effective when it is forward looking (Svensson, 2005; Faust & Wright, 2013). Achieving and maintaining price stability will be efficient and effective the better we understand the causes of inflation and the dynamics of how it evolves (Kohn, 2005). The ARCH/GARCH processes have been proved useful in modeling various economic phenomena and have received a great amount of attention in the economic literature (Lee & Kim, 2001). One goal of time series analysis is to forecast the future values of the time series data (Ping et al, 2013). Central banks forecast inflation considering all relevant factors (Hanif & Malik, 2015). The Reserve Bank of Zimbabwe (RBZ), being the central bank; can only have some control over future inflation. This is clear testimony to the fact that inflation forecasting is not unimportant in monetary policy making. In this study, we fit an AR (1) – GARCH (1, 1) model which has been shown to be indeed an AR (1) – IGARCH (1, 1) model. The study recommends the recognition of the IGARCH behavioral phenomenon exhibited by monthly inflation rates, if monetary policy design is anything to go by in Zimbabwe. Since the implications of IGARCH models are “too strong”, there is need for further research to consider fractionally integrated models such as the Fractionally Integrated GARCH (FIGARCH) model, Fractionally Integrated Exponential GARCH (FIEGARCH) model and the Fractionally Integrated APARCH (FIAPARCH) model amongst others; when analyzing inflation dynamics in Zimbabwe.

REFERENCES

12 The APPENDIX section is merged as follows: time series plot, residual plot, 95% confidence ellipse & 95% marginal intervals and the [shaded area] 95% confidence interval (forecast). The time series plot and the residual plot indicate volatility clustering of the series. The joint confidence regions (or the sets of confidence ellipse) generally indicate the region in which the realization of two test statistics must lie for us not to reject the null hypothesis. The forecast graph and the confidence ellipse indicate that the accuracy of our forecast is quite reasonable and acceptable since it falls within the 95% confidence interval.
