The College Admissions Contribution to the Labor Market Beauty Premium

DAVID ONG^* , MAN (AMANDA) XIE[†], AND JUNSEN ZHANG[‡]

February 6, 2020

Beautiful people earn more. Surprisingly, this premium is larger for men than for women and is independent of the degree of customer contact. Overlooked is the possibility that beauty can influence college admissions. We explore this academic contributor to the labor market beauty earnings premium by sampling 1,800 social media profiles of students from universities ranked from 1 to 200 in China and the US. Chinese universities use only standardized test scores for admissions. In contrast, US universities use also grades and extracurricular activities, which are not necessarily beauty-blind. Consistent with beauty-blind admissions, student's beauty is uncorrelated with the rank of their college in China. In the US, White men from higher ranked colleges are better-looking. As expected, the correlation is insignificant for White men who attended tech colleges and is highest for those who attended private colleges. We also find that White women and minorities of either gender are not better-looking at higher ranked colleges. Our evidence indicates a college admissions contribution to the labor market beauty premium for US White men, but not for students in China of either gender, White women, or minorities of either gender in the US, or for White men who attended technology colleges.

I. Introduction

Beautiful people earn more. Such is the conclusion of a burgeoning literature initiated by Biddle and Hamermesh (1994). Surprisingly, beauty seems to matter more for men than for women, and in most jobs, instead of being limited to those with extensive dealings with customers who might indulge a taste for beauty. (See A-Table 1 in the Appendix for a summary of the beauty premium for men and women across studies.) To explain these unexpected findings, several authors have proposed employer discrimination through the channel of human resource (HR) managers as a potential cause. However, overlooked is the possibility that the beauty premium originates prior to the labor market, specifically in the college admissions process, within which the discretion of teachers, guidance counselors, and admissions officers to discriminate, are comparable to that of HR managers. In fact, colleges seem to do precisely that when seeking talent in "leadership, performing arts, or athletics", all of which either influence or are influenced by popularity, and hence, by beauty among high school students.¹ In the case of the election of high school students to leadership positions, beauty may the crucial factor considering that the voting public (Berggren, Jordahl, and Poutvaara 2010) and even Ph.D. economists (Hamermesh 2006) exhibit a bias for beauty in the election of their leaders.

We test for this potential college admissions contribution to the labor market beauty premium by sampling 1,800 online social media profiles across a wide range of universities (ranked 1–200) in China and in the US. Given that US universities use extracurricular activities and grades in the decision to admit students (Green, Jaschik, and Lederman 2011), we hypothesize that the beauty of students may increase the rank of the university they attended in the US. In contrast, Chinese universities use standardized test scores almost exclusively to admit students (Bai and Chi 2014; Li et al. 2012; Yang 2014).² Despite the shortcomings of such an admissions system in terms of the stress it imposes on students (Cai et al. 2019), it is necessarily beauty-blind. In light of a recent

¹ According to a recent New York Times article (Cain 2017), 'Harvard's application informs students that its mission is "to educate our students to be citizens and citizen-leaders for society." Yale's website advises applicants that it seeks "the leaders of their generation". On Princeton's site, "leadership activities" are first among equals on a list of characteristics for would-be students to showcase. Even Wesleyan, known for its artistic culture, was found by one study to evaluate applicants based on leadership potential...Whatever the colleges' intentions, the pressure to lead now defines and constricts our children's adolescence....It seemed no activity or accomplishment meant squat unless it was somehow connected to leadership.'

https://www.nytimes.com/2017/03/24/opinion/sunday/not-leadership-material-good-the-world-needs-followers.html?_r=1

 $^{^{2}}$ A number of top-tier universities in China admit some outstanding students, e.g., winners of international mathematics competitions through special channels that involve the university's own admissions exams, followed by oral exam type interviews. However, details on the policies for specific universities are not publicly available.

large sample study of twins which finds no relationship between facial attractiveness and intelligence (Mitchem et al. 2015), we hypothesize that no association exists between the beauty of students and the rank of the university they attended in China.

Our hypothesis for China is confirmed: the facial beauty of Chinese students of either gender is uncorrelated with the rank of the college they attended. Our hypothesis for the US is confirmed only for White men (74% of our male sample). Only their facial beauty increases with the rank of college attended.

We test further the hypothesis that reliance on standardized tests diminishes the association between the beauty of students and the rank of the college that we find for White men by checking for variation in the magnitude of the correlation across different types of colleges. We separate our sample of White men according to whether they attended private, public, or technology colleges. Compared to public colleges, private colleges can rely less on standardized tests than public colleges, because they are less regulated. As expected, the association between facial beauty and the rank of the college attended is stronger for private colleges. On the other hand, technology colleges should attach more weight to technical ability as indicated by standardized test scores than non-technology colleges.³ Accordingly, we find that the association between beauty and the rank of the college attended is insignificant for technology colleges. Thus, reliance on standardized tests appears to suppress the correlation between the beauty of White men and the rank of their college, while discretion in admissions criteria increases it.

Our finding that the beauty of both genders in China, White women and non-White minorities of both genders in the US, and White men in tech colleges, is not associated with the rank of their college supports prior evidence that beauty is uncorrelated with intelligence. Our contribution to this literature on the association between intelligence and beauty is to provide further evidence against an association between beauty and general academic ability, as captured through the variation in the rank of colleges. For our sample of US White women and non-White minorities of both genders, we also provide evidence that beauty is not associated with non-academic criteria, e.g., leadership qualities and athletic ability, that US colleges also use for admitting students.

³ A former director of admissions at Dartmouth, an elite private college, revealed that it was very difficult to choose from among the many academically well-qualified candidates of the two thousand applications she read per year (Sabky 2017). In her view, personal essays by the candidate and letters of recommendation from illustriousness mentors are generally uninformative. Rather, she must resort to idiosyncratic signals such as "inappropriate email addresses", behavior on a campus visit, or an unusual recommender—in the case of the article--the janitor of the student's high school. Additionally, she sometimes give those signals greater priority than standardized test scores in her admissions decision. See: https://www.nytimes.com/2017/04/04/opinion/check-this-box-if-youre-a-good-person.html?mtrref=query.nytimes.com&assetType=opinion

We check for the simple association between the rank of the college attended and after graduation wages to get a sense of the potential economic importance of the college admissions contribution to the labor market beauty premium for White men. For our White men sample, a one percentage point increase in beauty rank corresponds to a two-college increase in the rank of the college attended. This correspondence translates in to a roughly six percent increase in salary 10 years after graduation for a 10 percent increase in beauty rank.

The association between beauty and earnings for White men that we find is of a similar magnitude to that previously found for the labor market beauty premium, which ranges from 5-20 percent for the coarser measure of below, at, or above average looks (A-Table 1). In principle, it is possible for the variation in the beauty of White men to be of comparable magnitude because, while these previous studies of the labor market beauty premium do control for years of education, they do not control for the rank of college among those who graduated from college.

In light of the previous finding that intelligence is not correlated with beauty, our finding of no significant correlation between the beauty of students and the rank of their college for students of both genders in China, White women and non-White minorities of both genders in the US, and White men in tech colleges suggest that the correlation we find for White men who graduated from non-tech colleges is not related to their academic ability. We discuss the potential channels through which the beauty of only White men may affect or be affected by their admissions to college after the main results.

We contribute to the literature on the labor market beauty premium by providing evidence which suggests a college admission contribution to the labor market beauty earnings premium for men in the US, who are mostly White.⁴ This college admissions contribution may help explain the surprisingly greater labor market beauty premium for men in the US, and why it does not vary across jobs with significant and insignificant exposure to customers. Our evidence suggests that the labor market beauty premium for men and women in China (Deng, Li, and Zhou 2019; Gu and Ji 2019; Hamermesh, Meng, and Zhang 2002; Maurer-Fazio and Lei 2015) and for women and non-Whites of both genders in the US may arise after college. Our results suggest the potential importance of controlling not only for the years of education in future studies of the labor market beauty premium, but also for the rank of the college attended, particularly for men.

II. Review of labor market studies on the labor market beauty premium

Several empirical studies have demonstrated a robust labor market beauty premium for workers around the world and in various sectors beginning with the seminal work of Biddle and Hamermesh (1994). The theories of labor market discrimination by beauty parallel those of other forms of labor market discrimination, e.g., by race. These fall under two broad categories: tastebased discrimination (Becker 1971), where the discriminated characteristic, in this case, beauty, enters directly into the utility function, and productivity-based or statistical discrimination (Arrow 1973), where the observable characteristic, also beauty, is correlated with the characteristic that that influences productivity. As an example of the taste-based discrimination, customers, e.g., purchasers of fashion magazines, can derive utility directly from better-looking workers. As an example of the latter statistical discrimination, employers may discriminate by hiring good-looking people because beauty signals pleasant manners and good social skills, which are not as immediately observable as beauty. Employers may value such skills because they either increase customer satisfaction or the productivity of other workers. Alternatively, consumers can use beauty to infer other characteristics, e.g., competence in doctors, because of a possible statistical relationship between beauty and cognitive and non-cognitive skills.

Since the inception of the literature, a notable and surprisingly larger beauty premium/plainness penalty has existed for men than for women (Borland and Leigh 2014; Doorley and Sierminska 2015; Hamermesh and Biddle 1994; Harper 2000; Mocan and Tekin 2010). Moreover, the importance of looks as revealed through employer surveys on the amount of interaction with customers show little explanatory power for the cross-sectional beauty premium (Doorley and Sierminska 2015; Hamermesh and Biddle 1994). See A-Table 1 in the Appendix. While the constancy of the beauty premium across jobs can be explained by employer discrimination, that would not seem to predict a larger premium for men than for women.

These unexpected findings highlight other potential problems in identifying the source of the labor market beauty premium. Other factors can increase a person's ability to make themselves more beautiful, which, in turn, increases their wages. For example, intelligence, which is generally associated with productivity in most jobs, can potentially increase the skill with which flattering clothes (which has been shown to add to the income of women (Hamermesh, Meng, and Zhang 2002)) are chosen. Alternatively, intelligence can free up more time from other tasks with which to choose these clothes. Intelligence can also increase confidence, which may enhance the

impression a person makes, e.g., if confidence in one's ability makes one smile more easily, and if smiling enhances attractiveness. Accordingly, more intelligent workers can appear more attractive, thereby earning higher wages, although they are not necessarily more physically attractive. Customers may not derive utility from the exceptional intelligence of those workers. Instead, these customers can derive utility from the friendliness of more confident workers, e.g., in a restaurant host/hostess.

Aside from intelligence, a myriad of other factors related to productivity including health and family income can conceivably contribute to both the beauty of workers and their wages. Thus, important confounders for both taste-based and statistical discrimination for the labor market beauty premium exist. In addition to the identification problems, the gender difference in significance can also be due to out-selection by attractive/unattractive women from the labor market, which again, is difficult to control for in empirical studies of the labor market.

To minimize the effects of statistical discrimination and out-selection, several researchers in the beauty premium literature used CV correspondence studies of employers. These correspondence studies are widely used to explore ethnic and gender discrimination (Bertrand and Mullainathan 2004). Such studies with employers can decrease the effects of these confounders through random assignment of beauty to the characteristics associated with beauty, e.g., intelligence, which is signaled by education in the CVs. Confirming prior empirical findings of a beauty premium, a CV correspondence study in Argentina finds that distorted photos of real people designed to make them ugly were much less likely to obtain a callback López et al. (2013). With the exception of the pronounced premium for better-looking women in office support, receptionist, and customer service jobs, the authors ascertained roughly the same positive premium for both genders across jobs, irrespective of the degree of customer contact.

A significant premium across all four occupations was observed in China, including areas such as software engineering, which has minimal customer contact (Maurer-Fazio and Lei 2015). A correspondence study in Israel using resumes with randomized photos of applicants with varying beauty shows that only better-looking men were more likely to receive a callback to a job application, whereas women suffered a beauty penalty in terms of callback rates, and even in jobs which, as the authors point out, beauty plays no obvious role: accounts management, budgeting, industrial engineering, and computer programming (2015). However, despite the many positive findings on labor market discrimination by beauty, the existing literature has largely ignored the possibility that the beauty premium may begin before entry into the labor market.⁵ The source of the beauty premium is important both to better understand labor market discrimination and also to better target antidiscrimination regulations based on personal appearance. Such legislation has already been enacted in some states and proposed elsewhere (Hamermesh 2011; Hamermesh and Biddle 1994).

The advantage of our study with respect to identification problems in the empirical and CV correspondence study literature is that we only look at the relation between beauty (as rated by impartial observers) and labor market productivity traits, as revealed by college rankings. Our raters are neither employers nor customers, either of whom might have a taste for beauty within particular industries (e.g., for very thin women in the modeling industry) or be concerned with unobserved productivity-related traits correlated with beauty. Thus, neither taste-based nor statistical discrimination by customers or employers are relevant to this study. Additionally, given that the profiles rated here are from pre-labor market university students, they are also less likely to be biased by those individuals who have systematically selected out of the sample by beauty for opportunities in the marriage market.

Few studies in economics are available regarding the relation between academic performance and beauty. Grade point average is predicted by physical attractiveness for grade school students of both genders in England (Hansen 2016) and for female but not for male students upon entering high school (French et al. 2009). However, the association between attractiveness and grade point average becomes negative for males and insignificant for females when personality and grooming are controlled for (French et al. 2009). High school facial attractiveness can account for the attractiveness premium up to the mid-30s (Scholz and Sicinski 2015). Within an elite women's liberal arts college, a negative correlation was found between beauty and academic productivityrelated traits, as measured by SAT scores (Deryugina and Shurchkov 2015). No correlation was found between beauty and productivity-related traits among lawyers who graduated from one law school (Biddle and Hamermesh 1998) and among experimental subjects (Mobius and Rosenblat

⁵ Many studies exist on the correlates of beauty in educational settings in the psychology literature. Physically attractive students receive higher grades in high school and college (French et al. 2009). Attractive individuals are consistently perceived or judged more favorably than the unattractive in a number of dimensions, including intelligence, academic potential, grades, confidence, extroversion, and various social skills (Jackson, Hunter, and Hodge 1995; Mobius and Rosenblat 2006; Ritts, Patterson, and Tubbs 1992). These studies suggest that beauty is believed to be correlated with these traits. However, they do not control for these traits in their identification of beliefs. Thus, they failed to demonstrate that beauty causes the beauty premium in the labor market.

2006). Most importantly, with respect to our hypothesis, these prior studies either of single colleges, or if not, they did not test for the effect of the attended university's rank. Consequently, they do not rule out that the labor market beauty premium in terms earnings was due to a potential bias in the college application process.

III. Methodology

We randomly selected 30 universities in China and the US ranked from 1 to 200. Each selected college has similar rankings in at least two commonly used ranking systems. The rankings for US colleges include the U.S. News & World Report Ranking,⁶ the Academic Ranking of World Universities (ARWU), ⁷ whereas the Chinese University Alumni Alliance Ranking (CUAA)⁸ and the Wu Shulian's Chinese University Rankings⁹ are for Chinese colleges. College rankings are shown in the A-Table 2 in the Appendix.

We randomly sampled 30 profiles (15 for each gender) for each school on Facebook. In the US, 72 percent of college students have a profile on Facebook.¹⁰ We used the social media site Renren in China, which had a reported membership of 280 million in 2013.¹¹ In both services, users can create profiles for free with photos, other images, list of personal interests, contact information, accounts of memorable life events, and other personal information, such as educational background and employment status. Registration on the two social media sites requires filling in: name, gender, and email address or phone number. Renren also requires a birth date and educational information (either high school or college). The educational information of a Renren account can also be "verified" by a school IP address or the school email. Such verification is indicated in the profile. We used only such verified accounts. A user is also required to upload a personal photo for the profile picture.

After registration, users can add other users as "friends" with whom they can share their profile content. Users can also join common-interest user groups which are organized by workplace, school, or other categories. Users determine who can browse their pages or receive their updates

¹¹ Renren is the Facebook analog for college students in China, as Facebook is blocked by the Chinese Government.

with their privacy settings. On both websites, users can make their profile "public," (anyone with a membership can see their profile) or "open to friends" (only "friends" can see their profile) or "private" (only the user themselves can view their profile). Both websites allow users to search for public profiles with specific educational backgrounds.

Search engines generally employ confidential proprietary algorithms to enhance the efficiency of searches. To avoid any unobserved influences from such algorithms on our results, we selected the profile photo based on random numbers from 1 to 200 generated prior to our searches. Hence, if we drew a number 67, we would select the 67th profile in the search engine results. We drew two sets of random numbers: the second to be used in cases where the profile indicated by the first number did not have the required information or photo quality.¹² Each selected profile was that of a student who graduated from the school as an undergraduate in 2012. The profile photo must be a clear color front-view photo without any head covering. Other people or backgrounds in the photos were cropped to highlight the face of the subject. We paid raters (5 RMB/100 pairs in China and 0.75 USD/100 pairs in the US) to evaluate all profile photos using a proprietary beauty rating program, which they could access through a standard web browser.¹³

The rating program matched each photo randomly with 10 other photos of the same gender in the same country. 4,500 photo pairs are generated for each gender in each country. We used multiple raters to rate the same photo. In the US, each photo was rated 12–37 times by US raters, with a mean of 22 times. In China, each photo was rated 12–28 times, with a mean of 20 times. Such rating frequencies are comparable to other studies (Deryugina and Shurchkov 2015). The final rating for each photo is based on the average rating of all raters of that photo. In total, 90 Chinese raters (60 male) rated all 900 Chinese photos, and 103 US raters (49 males, 86 White) rated all 900 US photos. The Chinese raters were graduate students recruited from the Peking University HSBC School of Business through a mass email. The US raters were recruited through Amazon Mechanical Turk, a project-based employment service offered by Amazon.

We also hired an additional 27 US raters to categorize the race (White, Black, Hispanic, and Asian) and age ranges (age categories: 23–26 and 27 or older) of all US photos. Chinese students are almost always of the Han majority and within the 23–26 age range because they rarely take

¹² These criteria are available on request.

¹³ At the time of writing, the exchange rate was 1 USD for 6.5 RMB. Given the few minutes it takes to rate all 100 photos, our payment was relatively high for both Mechanical Turk and China. A high wage was set to attract sufficient numbers of raters in a short time span.

time off before college.¹⁴ Unlike US Facebook profiles, age is listed with the Chinese profiles on Renren. Each US rater was asked to categorize 100 US photos. Each US photo was categorized once each by three different US raters. The final race and age categories of the US photos were determined by the ratings of the US majority raters, i.e., two or three out of three. The results of the race and age categorization for the US sample are shown in A-Table 4.

Raters were asked to choose the more physically attractive within each pair. Instead of asking raters for a numerical rating within a certain range of numbers, as is standard in the field (Hamermesh and Biddle 1994), we followed the methodology in Ong, Yang, and Zhang (2020) asked raters to decide only which photo of a pair is better-looking. Such a judgment may be easier and more precise than assigning a number to indicate how good-looking someone is according to a subjective numerical scale (Negahban, Oh, and Shah 2012).

Numerical beauty ratings can cluster around specific numbers, e.g., 7 or 8 out of 10. A given subject may not be consistent in their beauty ratings across a number of photos, because of fatigue, lapses in memory, or because their subjective reference benchmark level of beauty changes as they rate photos. In contrast, binary decisions require discerning only the minimal difference in beauty between two photos in side-by-side comparison. Subjects do not need to strain their memory to maintain the consistency of the ratings for photos with similar beauty, if these photos happen to have many other intervening photos. With a binary comparison, the accuracy of a subject's memory is no longer an issue. The binary decision also avoids potential scale differences across individuals, genders, and countries (e.g., where Chinese females choose higher numbers than American male raters), which can add noise to the data.

To deal with these sources of noise, prior studies coarsen their 1-7 scale data into three categories: below, at, or above average beauty. However, this may sacrifice the precision we exploit to establish our hypotheses below. Lastly, our reliance on the binary choices of raters means that our beauty ranking is a relative ranking within the sample, not a potentially out of sample/absolute ranking against unobserved subjective protypes of beauty that the subject has in mind and uses as a benchmark.

The software we developed aggregates the ratings for each photo into a continuous number between 0 percent (least attractive) and 100 percent (most attractive) using the well-established

¹⁴ The Han race constitutes 91 percent of the population of China, See <u>https://en.wikipedia.org/wiki/Ethnic_minorities_in_China</u>. The share of Hans is likely even higher among university students.

Bradley–Terry model for aggregating binary comparisons into a ranking (Bradley and Terry 1952). For each photo, these numbers represent the attractiveness percentile, namely, the share of other photos that reviewers on average found less attractive.

The following equation is estimated for each country:

$$Collegerank_i = \alpha + \beta_1(Rating_i) + \varepsilon$$
 Eq. (1)

where *i* is the index of individual students. *Collegerank_i* refers to the log of college rank within each country. *Rating_i* is a number between 0 percent and 100 percent representing the aggregate rating given by the raters. We invert the ranking, i.e., use $1 - Rating_i$ so that a smaller beauty percent number (high beauty rank) corresponds to smaller college rank number (high rank college). We abuse notation slightly and omit the inversion from the text. The *Rating_i* variable is derived from the residual of a regression in which we control for subject's age (using a dummy variable which takes on the value of 0 for the age range 23–26 and the value of 1 for 27 and older) based on the listed age of the profile in China, and the age attributed by the raters for profiles in the US. In this regression, we also controlled for display rank of the photo in the search engine results, which could be affected by the unobserved search algorithm.

IV. Results

The coefficient for *beauty percentile* (0.032) in column (1) of Table 1 is small and statistically insignificant indicating

Observation I. The beauty of students in China has no economically or statistically significant association to the rank of the college they attended.

We separate the data by gender because the correlation between beauty and ability can vary by gender. Columns (2) and (3) of Table 1 show that

Observation II. The beauty of men (0.0832) or women (-0.00931) in China has no economically or statistically significant association to the rank of the college they attended.

In contrast, column (1) of Table 2 indicates that the coefficient is not small for students as a whole (0.131) in the US, though it is still statistically insignificant due to the large standard error.

Observation III. The beauty of students in the US has no statistically significant association to the rank of the college they attended.

Similarly, columns (2) and (3) of Table 2 indicate that

Observation IV. The beauty of men (0.370) or women (-0.114) in the US has no statistically significant association to the rank of the college they attended in the US.

Thus, while the insignificant and near zero coefficients for students in China indicate a true zero effect of beauty on the rank of college attended, the larger but insignificant coefficients and along with large standard errors for students in the US implies that our estimates are imprecise. Such imprecision could be due to heterogeneous effects of the US student's beauty on the rank of the college they attended. In particular, the association between students' beauty and the rank of the college they attended can also vary by race, especially if colleges may seek different qualities from different races. White men and women make up the largest part (660/900 = 73%) of the sample. Figure 1 displays the plot of the beauty rank of students at a given college vs. the numerical value of college rank for US White men and women. The right panel shows that the men's beauty rank monotonically increases on the rank of the college attended, whereas the left panel shows that of women does not.

Column (4) of Table 2 reveals that *college rank* becomes significant for Whites (0.441) and columns (5) and (6) reveals that this trend is driven by White men.

Observation V. The beauty of White men (0.740), but not White women (0.126) significantly increases with the rank of the college attended in the US.

The 0.740 coefficient for *log* college rank suggests that for every percentage point increase in beauty rank, there is a $2.1=e^{0.74}$ increase in the rank of the college attended. The significance of the coefficient of college rank for White men and the insignificance for White women hold also when we use college rank without the log transformation.

We hypothesize that the correlates of beauty might affect admissions in the US through the exercise of discretion as to the merits signaled by extracurricular activities. According to this hypothesis, we should find a greater association between beauty and the rank of the college attended for private colleges, which have greater discretion because they are less regulated. To test

this hypothesis, we redo the previous regressions by comparing results without and with only private colleges (namely, Harvard, Columbia, Penn, Massachusetts Institute of Technology, New York University, Boston University, Stevens Institute of Technology, Illinois Institute of Technology, and New Jersey Institute of Technology) in Table 3. The coefficient for beauty rank increases from 0.339 in column (1) for public colleges to 1.726 in column (2) for private colleges, suggesting that an incremental increase in the beauty rank is associated with a greater increase in the rank of college attended among private colleges. This greater association is confirmed in column (5) with the positive coefficient for the interaction of the private dummy variable and beauty rank (1.388) for the full sample of both private and public colleges.

These results suggest that the correlates of beauty have a larger effect on the rank of colleges for students who attended private colleges. For White men who attended private colleges, a one percent increase in beauty rank corresponds to a $5.6=e^{1.726}$ increase in the rank of the college attended or an almost two percent increase in salary for a one percent increase in beauty rank. The negative coefficient for private college without interaction with beauty (-3.105) indicates that on average, White males who attended private colleges are *less* attractive.

This finding of a higher slope for the regression of college rank on beauty along with a lower intercept for private as compared to publics colleges raises the possibility that private colleges can themselves be more heterogeneous than public colleges in terms of how much the correlates of beauty affect the chance of admissions of White men. A potential reason for the greater level of heterogeneity among private as compared to public colleges is, higher ranked private colleges might have a greater latitude and need to resort to soft criteria in order to reject more otherwise similar high-quality students, while lower ranked private colleges may use their greater discretion to admit more marginal candidates.

To test the hypothesis that higher ranked private colleges are more selective than lower ranked private colleges in terms of beauty or its correlates, we drop the top four private colleges from our sample: Harvard, Columbia, Penn, MIT, that are 'top-10' in column (3), while leaving in the bottom five private colleges in the sample. The coefficient decreases to 0.289. If we drop the bottom four ranked private colleges: Boston University, Stevens, IIT, and NJIT in Column (4), the coefficient increases to 0.814. These results suggest that beauty or its correlates may have a much larger effect for admissions to the top private colleges than to the lower ranked private colleges.

Columns (6-8) show results for technology colleges, which may rely less on discretion and more on standardized tests. This conjecture is confirmed by 1) the contrast between the significant coefficient for beauty rank (0.836) in column (6) which drops technology colleges and the insignificant coefficient for beauty rank (0.256) in column (7) which contains data only from technology colleges and 2) by the insignificance of the technology beauty rank interaction in column (8).

Table 4 shows that the coefficients for non-White races of either gender are negative, but too imprecisely measured to be statistically significant. This lack of significance does not seem to be due to the sample sizes being smaller than that of Whites, however. For non-White men and women, we have 119 and 121 observations, respectively. Both are nearly twice as large as the number of observations that we have for White men in private colleges for column (2) of Table 3, which was still significant at the 5 percent level. However, many of the sample sizes for the coefficients for the correlation of disaggregated minorities in columns (3)-(8) are too small to draw any inference. Hence, we make an observation for the non-Whites, and merely remark that the disaggregated data is consistent with the aggregate.

Observation VI. The beauty of non-Whites (Black, Hispanic, or Asian students) in the US have no statistically significant association with the rank of the college they attended.

These findings of no significant correlation between the beauty of students and the rank of their college for students of both genders in China, White women and non-White minorities of both genders in the US, and White men in tech colleges, suggests that the correlation we find for White men is due to non-academic factors used in the admissions process. We discuss some potential non-academic factors in the admissions process which might interact with the beauty of White men, in particular, in the Discussion and Conclusion section.

We perform a simple regression of the median and the expected salary (not broken down by race or gender) on college rank to obtain a rough estimate of the economic impact of beauty on earnings. An incremental increase in college rank for a student enrolled in 2001 increases their expected salary by 139 USD and actual median salary 172 USD per year in 2011. (See A-Table 2 for the data.) Thus, a one percentage point increase in beauty rank corresponds to an increase in expected salary of 0.6 percent (2*139/42,740 USD) in mean salary and a 0.4 percent (2*172/41,500 USD) per year in median salary.

This association, and therefore, potential effect of beauty, is sizeable when compared to prior studies which use coarsened ratings: below, at, or above average looks. When we categorize our ratings into bottom-, middle-, and top-, our findings suggest that a 33 percent increase in beauty rating would result in a 24 percent increase in salary. Given that the data we use are based on salaries 10 years after graduation, differences in salary across colleges of different rank can also be due to increasing returns from graduating from higher ranked colleges. However, the change in expected salary per increase in the rank of the college attended is approximately 0.3% (137/42,740), which is similar to new graduates in China (0.25%).¹⁵ The effect of college rank on salary may also be large because our beauty data are across-colleges and can tend toward picking up across-industry effects, whereas prior studies are generally within-college or within-industry.

V. Discussion and Conclusion

We find, aggregating across genders, the beauty of students does not have an economically or statistically significant effect on the rank of the college they attended in China either as a whole (Observation I) or when separated by genders (Observation II). The statistical insignificance held also for US students as a whole (Observation III) and when we separated by gender (Observation IV). However, facial beauty is significantly associated with the rank of the college attended for White men, but not for White women (Observation V). The association for White men is strongest for higher ranked, and presumably, less regulated private colleges (Table 3). In contrast, the beauty of students in technology colleges has no significant association with the rank of the college.

A one percentage point increase in the beauty rank of White men is associated with a two-college increase in the rank of college attended. Such an advantage corresponds to roughly a 0.6 percent increase in salary 10 years after graduation using the salary of the lowest ranked college as the benchmark. When we categorize into three categories (top-, middle-, bottom-thirds), this association seems sufficient to explain the previously found labor market beauty premium which ranges from 5-20 percent for the coarser measure of beauty: below, at, or above average looks (A-Table 1).

Importantly for interpreting these results, our finding in China suggests that beauty is not statistically significantly associated with college rank. This outcome suggests that academic

¹⁵ Data available on request.

ability, at least as measured by standardized tests, is not associated with beauty. Our finding that the beauty of White women's and non-Whites of either gender is not correlated with the rank of the college they attended in the US suggests, moreover, that academic ability in general, not only as measured by standardized tests, but also including that measured by grades, letters of recommendation, is also not necessarily associated with beauty. This lack of correlation for White women and non-Whites of either gender suggests that the beauty premium we find for White men is the result of non-academic factors which might specifically benefit White men in the admissions process.

An important question for the validity of our positive results for White men in the US is whether there was self-selection into social media by beauty. It is beyond the scope of this study to address this question directly. However, we have a number of benchmarks groups to help mitigate this concern. If men tend to self-select into social media by beauty and the rank of their college, we would also expect that they would in China, and that White women, non-White minorities, and White men at technology colleges also would in the US. But, these groups apparently do not. We know of no basis to suggest that only White men who attended non-technology colleges in the US would self-select according to their beauty on to social media. Hence, the possibility that our results for White men are driven by self-selection seems implausible, or at least, less plausible than other alternatives, which we discuss below.

Another potential issue with our data is reverse causality. We use photos of graduates from 2012. The corresponding photos could have been taken in 2012 or even later, and likely much later than the year in which the admission decision was made. Consequently, the rank of the college attended can potentially affect the beauty rank if the college rank increases salary, and salary increases beauty by rendering better grooming and clothing more affordable. Again, if the direction of causality were reversed, we should find a similar association between the college rank and beauty in China, where graduates of higher ranked colleges earn comparably higher salaries, or for White women, non-White minorities, and White men in technology colleges in the US. However, we find no such association for members of these other groups.

As to why better-looking White men in particular may be favored in the admissions process, a correspondence study in Israel offers a potential clue (Ruffle and Shtudiner 2015). They find a beauty premium only for men, and surprisingly, a beauty penalty for women. Notably, this beauty penalty was driven by firms using in-house HR personnel, who they also find, are almost always

younger women. The authors infer that the bias against hiring more beautiful women is driven by female sexual jealousy.

Such a bias could also exist in the admissions process for elite colleges. The potential favoritism of teachers or admissions officers and alumni who interview candidates for better-looking male students can help explain our findings for men, especially if the interviewers tend to be female and White themselves, given a same-race bias among women (Hitsch, Hortaçsu, and Ariely 2010).¹⁶ This possibility of teacher or admissions interviewer bias for better-looking men is especially important for elite colleges, like Harvard, which rely heavily upon interviews in the admissions process, particularly for athletes (Arcidiacono, Kinsler, and Ransom 2019). However, there is no need to posit a pervasive self-serving taste-based discrimination on the part of the people involved in the admissions process to explain our results.

It is widely known and often openly acknowledged that colleges favor admitting athletes. For example, in one survey, 28 percent of four year college admissions directors in the US acknowledged using lower standards to admit athletes (Green, Jaschik, and Lederman 2011). Colleges do so because they benefit from favoritism to male athletes. High-ability athletes bring positive attention to their college by helping to win intercollege sports competitions. Such attention increases alumni donations (Anderson 2017; Meer and Rosen 2009), the number (McCormick and Tinsley 1987) and quality of applicants (Pope and Pope 2014; Tucker and Amato 2006), and allows the university to charge a higher tuition (Alexander and Kern 2009). Moreover, if HR managers at elite firms discriminate by athletic ability (Rivera 2011), colleges can improve their placement record by discriminating similarly in their admissions decisions.

In the case of Harvard, recruited athletes are admitted with drastically lower academic standards. Such lower standards result in an admissions rate of 86% for recruited athletes, which is over 14 times higher than for students who are not recruited athletes. As a consequence, recruited athletes make up over 10% of the admitted class though they are 1% of the applicant pool. Importantly for explaining our findings, 70% of admitted recruited athletes at Harvard are White (Arcidiacono, Kinsler, and Ransom 2019).

Hence, the favoritism colleges show towards athletes can help explain why we find that White men are better-looking in higher ranked colleges in the US, especially at elite private colleges.

¹⁶ http://data.worldbank.org/indicator/SE.PRM.TCHR.FE.ZS

Selecting for top-male athletes may also select for male beauty. The key factor which connects athletic ability and male beauty is prenatal exposure to androgens. The second-to-fourth digit length ratio (2D:4D) has been proposed as measure of prenatal exposure to androgens. A low 2D:4D ratio is associated with a large body size (Klimek et al. 2014), greater lean body mass (Schroeder et al. 2012), a more dominant personality (Neave et al. 2003), a greater propensity for risk taking (Apicella, Carré, and Dreber 2015), success as finance traders (Coates, Gurnell, and Rustichini 2009), and a higher level of facial masculinity (Pound, Penton-Voak, and Surridge 2009). Larger size, leaner body mass, greater risk taking, and more domineering personality likely confer advantages in competitive sports. Hence, it has been found that a low 2D:4D ratio is a predictor of athletic prowess and success in highly competitive sports (Coates, Gurnell, and Rustichini 2009; Hönekopp and Schuster 2010), including within the college varsity sports setting (Giffin et al. 2012). Therefore, a preference for admitting male athletes, especially for the most popular varsity sports, e.g., football and basketball, likely selects for these physical and psychological traits—as well as height. The selection for higher levels of these stereotypically male features likely increases with the rank of college, because higher ranked colleges can draw from a larger pool of applicants.

Though the digit ratio of competitive female athletes are also lower than non-athletes (Giffin et al. 2012; Hönekopp and Schuster 2010), there is little evidence to suggest that prenatal testosterone also contributes to the female facial attractiveness which we measure. We are unaware of any other organic connection between traditional female facial attractiveness and athletic ability. Hence, given the connection between male athletic ability and male beauty made by male androgens and the preponderance of White men among male athletes, the preference colleges show towards athletes can help explain our finding that only White males are better-looking at higher ranked colleges in the US, but not White females or minorities.

In addition to selection for better-looking men through the preference for athletes, universities may also implicitly select for better-looking men when they select for applicants with demonstrated leadership experience. Leadership contests among high school students may well be little more than popularity contests, and beauty increases popularity (Gu and Ji 2019). Moreover, athletic ability, height, a large lean body, facial masculinity, and a daring and domineering personality, may complement the stereotypically masculine traits of leaders in the West, and thereby, contribute to the charisma and confidence expected of leaders, especially among

adolescents (Mobius and Rosenblat 2006). White students from rich families may be overrepresented among applying students showing high leadership potential. White students from rich families are the majority at elite private high schools. Private high schools are smaller than public high schools and tend to have more leadership opportunities (Arcidiacono, Kinsler, and Ransom 2019). Thus, a potential reason why we find a significant correlation between the beauty of only White men and the rank of the college they attended is that White women and other racial minorities may be less able to exploit the favoritism colleges show towards students with leadership experience in the admissions process.

In summary, we do not find a significant correlation between the beauty of students and the rank of the college they graduated from for Chinese students of either gender, White women and non-White minorities of either gender, or for White men who graduated from technical colleges. In light of the previous finding that intelligence is not correlated with beauty, our finding would further suggest that beauty is not correlated with academic ability, as measured by college ranking, we do find a significant positive correlation between the beauty of White men and the rank of the college they attended, if they attended non-technical public or private colleges, with the strongest correlation for those who attended private colleges. We suggest that a potential channel of the college admissions contribution to the labor market beauty premium for White men may due the favoritism colleges show in the admissions process towards athletes or leaders of high school clubs. Our evidence suggests that the labor market beauty premium for men and women in China and for White women and non-White minorities of either gender in the West originates in the labor market, while that of White men may have a college admissions contribution.

A-TABLE 2: US UNIVERSITIES

Notes: The median salary data is the salary of alumni in 2011 who enrolled in 2001. The data is from the US Department of Education College Scorecard, which collected from The Economist magazine's website: we

College Scorecard, which we collected from The Economist magazine's website: <u>http://www.economist.com/blogs/graphicdetail/2015/10/value-university</u> The mean salary is the expected salary in 2011 calculated by The Economist, using a number of controls, again based on data from the US Department of Education College Scorecard. The difference between the median and the mean salaries is a measure of value added by the college.
