Abstract

If asset price risk-return relations vary over time based upon changing economic states, standard unconditional models may "wash out" state dependence and fail to identify that additional risk is contingently compensated with higher return. We address this matter by considering conditional risk-return relations for currency portfolios. Doing so within a data rich environment, we also develop broad based measures of investor risk. In general we find that agents require positive compensation for risks in some times and for some investment strategies. Our results identify that relations between currency returns and risk vary over time. Also we find that there are positive risk-return relations on momentum and value currency portfolios during the financial crisis. Furthermore, the risk-return relation on the momentum portfolio is counter-cyclical.

1. Introduction

Central to empirical asset pricing is testing the empirical relationship between risk and return, given that investors require compensation if risk is priced. A one-to-one relationship between returns and volatility, frequently used to map risk is also indicative of a constant Sharpe ratio. Despite its centrality to asset pricing, the literature has not yet converged on a consensus on the nature of the link between returns and risk factors, such as volatility. For stock market returns, French et al. (1987), Merton (1987), Scruggs (1998), Ghysels et al. (2005), and Guo and Whitelaw (2006) present positive risk-return relations for example, while Campbell (1987) and Glosten et al. (1993), Ang et al. (2006) report a negative empirical relationship between returns and risk in the form of return volatility.[1]

This study extends the risk-return trade-off test to the underexplored area of currency portfolios. Asset pricing studies usually focus upon U.S. stock market returns, but testing the risk and return nexus using alternative asset classes may provide enlightening results. In parallel, a burgeoning literature has recently implemented portfolio approaches for the currency market. These approaches, such as currency carry trades, sort currencies based upon cross-sectional differences, and has the advantage that currency specific components are averaged out (e.g. Lustig and Verdelhan, 2007; Lustig et al., 2011; Menkhoff et al. 2012a). Currency carry trades are widely investigated and currency carry portfolios have similarities to stock markets, that is to say both portfolios command downside risk (Atanasov and Nitschka, 2014; Dobrynskaya, 2014; Lettau et al., 2014).

Our study's first contribution is to focus on currency portfolios when examining the link between risk and return for several investment strategies. Some studies investigate risk-return for currency carry portfolios. Christiansen et al. (2011) and Menkhoff et al. (2012a) report that global currency volatility is associated with cross-sectional pricing models, while Bakshi and Panayotov (2013) explore the relationship in the time-series context. We also focus upon time-series relationships and extend the study of Bakshi and Panayotov (2013) to a wider array currency portfolios, not only the currency carry but also value and momentum investment strategies. Hence, our work not only considers the carry strategy for currency portfolios, we extend the examinations of currency risk and return to several

[1] Bali and Engle (2010) highlight that covariance between market and stock portfolios bears a positive risk premium.

currency investment strategies. Important recent work by Asness et al. (2013) argues that value and momentum are observed in all asset classes including currency markets. Kroencke et al. (2014), and Barroso and Santa-Clara (2015) present empirical results that including value and momentum currency portfolios diversify the risk of currency investors' portfolios. Menkhoff et al. (2012b) report that high average returns of currency momentum portfolios cannot be explained by traditional risk factors, although they do not specifically investigate the risk-return relationship in a time-series context. It is worthwhile, therefore, to ask the following question: What do the higher average returns of momentum portfolios imply for the risk-return trade-off?

Moreover, currency value portfolios are often associated with mean reversion to Purchasing Power Parity, an important way to understand exchange rate fluctuations (e.g. Taylor, 2002; Imbs et al., 2005; Boudoukh et al., 2016; Menkhoff et al., 2017). Although most studies focus on a time-series and single currency context, our work represents the first attempt to connect currency value portfolios to an intertemporal risk-return relationship. Furthermore, most professional currency fund managers employ one of three strategies, as reported by Pojarliev and Levich (2010), and hence it is important to understand the link between risk and return in the three currency investing strategies.[2] In contrast to Menkhoff et al. (2012a) and Menkhoff et al. (2017), we explore the intertemporal relation and it is more useful for investors in terms of risk management, since they do not observe the risk associated with their portfolios in the next month and frequently use past volatility as a risk proxy. Furthermore, we investigate four new currency portfolios: dollar carry trade (Lustig et al., 2014), global imbalance (Della Corte et al., 2016), good carry trade (Bekaert and Panayotov, 2019), and foreign exchange rate correlations (Mueller et al., 2017).

The second key contribution of our work is to take into account a time-varying relation between conditional volatility and expected returns. A theoretical asset pricing model conditional upon economic states was proposed by Backus and Gregory (1993). Conditional models have also been widely investigated in the stock market literature (e.g. Whitelaw, 2000; Rossi and Timmermann, 2010; Ghysels

[2]Three currency investing strategies are categorised as carry, momentum, and value: carry seeks to exploit the difference between high and low yielding currencies; momentum exploits trends in currency returns; and value seeks to a currency which is inexpensive in terms of the fundamental price.

et al., 2014; Adrian et al., 2019).[3] Whitelaw (2000) builds a general equilibrium model with a regime-switching consumption process and generates a time-varying and non-linear relation between volatility and expected returns in the stock market. Rossi and Timmermann (2010) find a non-monotonic relation between conditional volatility and expected returns in the stock market, and Ghysels et al. (2014) present work indicating that the positive risk-return relation is not observed in a "flight-to-quality" regime. In recent work, Adrian et al. (2019) find that expected returns on stock and bond markets depend upon the level of VIX and the relationships are nonlinear. To investigate the time-varying relationship between returns and risk, our study adopts a time-varying conditional factor model proposed by Ang and Kristensen (2012), which allows for smooth changes in coefficients.

The third contribution of our work is that when considering currency risk and return we employ an empirical factor model to summarize more broadly macroeconomic and financial market information. This is important since economic states affect the relationship between conditional volatility and expected returns, see Backus and Gregory (1993). To capture economic states, we focus upon the common component of macro and financial information since it is non-diversifiable and linked to the business cycle (Jurado et al., 2015), while idiosyncratic information can be diversified. Furthermore, narrow macro indicators like consumption may suffer from measurement errors, with an unknown relationship between macro indicators and asset returns. Investors also extract macro-finance information broadly when implementing their investment strategies. Ludvigson and Ng (2007) construct several empirical factors that summarise macroeconomic indicators and uncover a positive risk-return relation for U.S. stocks. This factor model is also useful in predicting currency carry returns (Filippou and Taylor, 2017). In contrast to the previous literature, our study predicts conditional FX market volatility by the factor model, not currency portfolio returns. Moreover, our aim is to examine the risk-return relationship with currency portfolios, rather than predict FX volatility.

To preview our results, we find that the relationship between conditional volatility and expected returns is time-varying on currency momentum and value portfolios. Importantly, we do not find formal evidence of a link between returns and risk on the currency momentum and value portfolios with constant

[3] For conditional asset pricing models more generally see inter alia Ferson and Schadt (1996), Lewellen and Nagel (2006) and Gagliardini et al. (2016).

parameter models. When we reflect changes in economic states and adopt the time-varying model, we observe that the risk-return parameters occasionally change signs, indicating that agents require positive compensation for risk in some periods but not in others. Moreover, the risk-return parameters increase during the recent financial crisis on the currency momentum and the currency value portfolios, and these indicate that average high returns of the momentum and the value portfolios are explained by the standard risk-return relationship. Our empirical findings are also associated with those of Guiso et al. (2018) who use Italian investors' survey data in 2007 and 2009, and observe that investors' risk aversion increased after the financial crisis.

The rest of the paper is organized as follows: Section 2 introduces the theoretical model. Section 3 describes the currency volatility and currency portfolios. Section 4 then lays out the econometric methods implemented in our paper, and Section 5 describes the data. Section 6 presents empirical results, Section 7 conducts the further analysis and, and Section 8 concludes.

2. A theoretical framework for risk-return trade-offs

This paper adopts a no-arbitrage asset pricing model to investigate the relationship between FX volatility and expected returns on currency portfolios. Following Backus et al. (2001) and Lustig et al. (2011, 2014), the logarithm of pricing kernel in currency i at $t+1$, m^i_{t+1}, is determined by a global state variable, z_{t+1}:

$$m^i_{t+1} = a^i + b^i z_{t+1} + u^i_{t+1} \tag{1}$$

where a^i is a parameter, b^i is the factor loading, and u^i_{t+1} is the idiosyncratic IID Gaussian shock.[4] Proposition 1 in Backus et al. (2001) states that if there are no arbitrage opportunities, the change in the exchange rate (Δs^i_{t+1}) between two currencies, say USD and GBP, is equal to the difference between their pricing kernels, respectively m_{t+1} and m^i_{t+1}, and therefore is a function of the global state variable

[4] For instance, we consider global industrial production or global inflation as examples of the global state variable which affects all pricing kernel. Backus et al. (2001) do not include the idiosyncratic shock, while this difference does not affect our conclusion.

z_{t+1}, based upon Equation (1):

$$\Delta s^i_{t+1} = m_{t+1} - m^i_{t+1} = a - a^i + (b - b^i)z_{t+1} + u_{t+1} - u^i_{t+1} \tag{2}$$

where the two idiosyncratic shocks u_{t+1} and u^i_{t+1} are IID with the variance σ^2_u. Furthermore, the conditional variance of the change in the exchange rate is also the difference between the two pricing kernels, and written as:

$$var_t(\Delta s^i_{t+1}) = (b - b^i)^2 var_t(z_{t+1}) + 2\sigma^2_u. \tag{3}$$

Using Equation (3), we can obtain aggregate conditional variance of the change in the exchange rate:

$$\sigma_{FX,t} = \frac{1}{K}\sum_{i=1}^{K} var_t(\Delta s^i_{t+1}) = (\frac{1}{K}\sum_{i=1}^{K}(b - b^i)^2)var_t(z_{t+1}) + 2\sigma^2_u. \tag{4}$$

This is an affine transformation of the state variable $var_t(z_{t+1})$ from Equation (3). Following Lustig and Verdelhan (2007), the risk premium of the currency portfolio is described as the covariance between the expected return of the currency portfolio and the logarithm of the pricing kernel:

$$E_t(r^i_{t+1}) = -cov_t(\Delta s^i_{t+1}, m_{t+1}) = \gamma^i var_t(z_{t+1}) + \sigma^2_u \tag{5}$$

where $\gamma^i = b(b-b^i)$ corresponds to the estimated coefficient of the regression between conditional variance and expected returns. The parameter γ^i could be positive or negative based upon the underlying link between the stochastic discount and state factors. Thus, to examine conditional risk-return trade-offs for currency portfolios, we implement an empirical variant of Equation (5) in the following analysis.

3. Currency portfolios and volatility

This section describes the currency volatility and currency portfolios data used in our study. To examine trade-offs for a wide range of currency returns, we construct several currency portfolios. These include, carry, momentum, value, good carry, dollar carry trade, global imbalance, and foreign exchange rate correlation.

3.1. *Currency excess return and volatility*

This study computes a currency excess return using spot and forward rates and assuming U.S. investors. The currency excess return $r_{i,t}$ for currency i at time t is defined as:

$$r_{i,t} = \frac{F_{i,t-1} - S_{i,t}}{S_{i,t}} \tag{6}$$

where $F_{i,t-1}$ is the forward price of foreign currency i per unit of U.S. dollar and this price is agreed at $t-1$ and delivered at t, and $S_{i,t}$ is the spot price of foreign currency i at t. Following Lustig et al. (2011), we take into account transaction costs using bid-ask prices.

We adopt global FX volatility as our measure of volatility in intertemporal risk-return trade-off tests. We follow Menkhoff et al. (2012a) and global FX volatility, σ_{FX}, in day d is obtained as:

$$\sigma_{FX,d} = \sum_{i=1}^{K_d} \left(\frac{|r_{i,d}|}{K_d} \right) \tag{7}$$

where $|r_{i,d}|$ is the absolute value of $r_{i,d}$, and K_d is the number of currencies on day d. Next, monthly global FX volatility in month t, $\sigma_{FX,t}$, is calculated as:

$$\sigma_{FX,t} = \frac{1}{T_t} \sum_{d=1}^{T_t} \sigma_{FX,d} \tag{8}$$

where T_t is the total number of trading days in month t. The monthly global FX volatility $\sigma_{FX,d}$ is employed in the later analysis.

3.2. *Carry strategy*

We employ three currency portfolios and begin with carry trade portfolios which are constructed based upon forward discounts. This strategy exploits deviations from uncovered interest rate parity, previously explored in the literature (e.g. Lustig et al., 2011; Menkhoff et al., 2012a; Bakshi and Panayotov, 2013). A high interest rate currency generates a higher return than a low interest rate currency because the interest rate difference is not offset by the change in the spot exchange rate. Following Lustig et al. (2011), a forward discount $FD_{i,t}$ is computed as the difference between forward and spot rates at time t:

$$FD_{i,t} = \frac{F_{i,t} - S_{i,t}}{S_{i,t}}. \tag{9}$$

When $FD_{i,t}$ is positive, this means that the interest rate in the foreign country i is higher than that in U.S., since we assume that the covered interest rate parity condition is satisfied (e.g. Akram et al., 2008). In carry portfolios, investors go long (short) in currencies in which there are high (low) forward discounts. This study considers strategies at a monthly frequency. At the end of each month, two currencies are in the long position and two currencies are in the short position.[5]

In addition to the standard carry strategy, we adopt the good carry trade strategy. This strategy is proposed by Bakaert and Panayatov (2017) who find that only a limited number of currencies avoids negative skewness and enhance portfolio's Sharpe ratio. Following Bakaert and Panayatov (2019), we employ GBP, NZD and SEK.

3.3. *Momentum strategy*

A momentum strategy uses past return as a characteristic, instead of a forward discount. We employ the past three months cumulative currency excess return. Kroencke et al. (2014) and Barroso and Santa-Clara (2015) also adopt this definition, since Menkhoff et al. (2012b) report that momentum has persistence, but that including longer than the past three months do not provide a higher return. In momentum portfolios, long (short) currencies have high (low) past excess returns.

3.4. *Value strategy*

A value strategy exploits information of a fundamental value: and if the price of currency i is undervalued compared with what is considered its fundamental value, then investors invest in the currency i. This strategy focuses upon deviation from Purchasing power parity (PPP), and a value of the exchange rate has a mean-reversion property in the long-run (e.g. Taylor, 2002; Boudoukh et al., 2016). The fundamental value is computed as the cumulative five year change of the real exchange rate as in Kroencke

[5]We also go long (short) in three currencies in the Appendix.

et al. (2014) and Barroso and Santa-Clara (2015). The fundamental value $VA_{i,t}$ is computed as:

$$VA_{i,t} = \frac{S_{i,t-3}CPI_{i,t-60}CPI_{US,t-3}}{S_{i,t-60}CPI_{i,t-3}CPI_{US,t-60}} \tag{10}$$

where $CPI_{i,t-3}$ is the price level of consumer goods in country i at $t-3$, and $CPI_{US,t-3}$ is the price level in the U.S. We follow Kroencke et al. (2014) and employ a three month lag to avoid overlaps between momentum and value strategies. Further, Barroso and Santa-Clara (2015) document that a lag value is appropriate since there is a time lag involved in the observation of price levels. If $VA_{i,t}$ is higher (lower) than one, then this it indicates that the currency is overvalued (undervalued), and thus is in the short (long) position.

3.5. *Dollar carry trade*

The dollar carry trade is based upon the Average Forward Premium (AFD) which is calculated as the average forward discount on foreign currency against the U.S. dollar (Lustig et al., 2014). We go long in foreign currencies when AFD is above the U.S. short-term interest rate and go short otherwise.

3.6. *Global imbalance*

Global imbalance (IMB) portfolios are proposed by Della-Corte et al. (2016). This factor is based upon the theory that net debtor countries are riskier than net creditor countries, and hence these countries' currencies provide risk premia. In particular, the net debt countries which are funded by foreign currencies are riskier than those are founded by their own currencies. The global imbalance factor is constructed by the two steps (Della-Corte et al. 2016). Firstly, currencies are assigned into two baskets based upon the net foreign asset to GDP ratio (nfa). The data of foreign assets and liabilities, and gross domestic product (GDP) are shared by Lane and Milesi-Feretti (2004, 2007). Secondly, currencies are assigned into three baskets within each nfa basket based upon the share of foreign liabilities in domestic currency (ldc). Data of the proportion of external liabilities denominated in foreign currency are constructed by Lane and Shambaugh (2010), and Benetrix et al. (2015). Portfolio 1 includes high nfa and high ldc countries, which are robust against negative financial shocks, while Portfolio 5 does low nfa and low ldc countries, which are risky and provide risk premia. Therefore, the global imbalance factor is calculated as the return spread between portfolios 5 and 1.

3.7. *International correlation risk*

We also adopt the international correlation risk (ΔFXC). Following Mueller et al. (2017), we calculate it as follows. First, a conditional correlation between FX spot rate returns is obtained and the rolling window size is three months (66 days). Second, we sort all G10 FX pairs (base currency is the U.S. dollar) into deciles based on conditional correlations and take the difference between the average correlation in the top decile and that in the bottom decile. This is called as the cross-sectional dispersion in conditional FX correlation (FXC). Third, we pick up FXC at each end of month and take the innovation part of FXC (ΔFXC). Fourth, we construct three currency portfolios based upon factor betas on ΔFXC. The factor betas are estimated by regressing on currency excess returns on ΔFXC, and the rolling window size is 36 months. It means that the portfolios are rebalanced each month. Finally, the international correlation risk portfolio is constructed by taking the return difference between portfolios 1 and 3.

4. Empirical methodology

This section describes the econometrics methods used to test risk-return trade-offs in FX markets, and to identify the time varying risk-return parameter. We employ a factor model to summarise a large information set based upon many macroeconomic indicators. Regressing FX volatility onto common factors, we obtain predicted FX volatility. Furthermore, we use a conditional factor model that allows for a change in risk-return relationship.

4.1. *Factor model*

We begin by explaining the way in which we obtain common information, which underpins our volatility measure. The common information across macroeconomic data sets is extracted by principal components. Define $\mathbf{X}$ to be the $T \times N$ standardized macroeconomic time series matrix with elements, $x_{j,t}$, $j = 1, \ldots, N$, $t = 1, \ldots, T$, and N indicates the number of macroeconomic time series and T does that of time series observations. Each macroeconomic time series, $x_{j,t}$, is decomposed into a common factor, f_t, and an idiosyncratic component, $\epsilon_{j,t}$, as:

$$x_{j,t} = \Lambda_j f_t + \epsilon_{j,t} \tag{11}$$

where Λ_j is the loading on the common factor.

Given the estimated common factors in Equation (11), we employ a factor model to obtain conditional volatility, since adopting many conditional variables faces a dimensionality problem. Following Ludvigson and Ng (2007), FX volatility, $\sigma_{FX,t+1}$, is regressed onto a common factor f_t and an error term e_{t+1}:

$$\sigma_{FX,t+1} = \phi f_t + e_{t+1}. \tag{12}$$

Once we estimate the parameters ϕ, we obtain predicted FX volatility $\hat{\sigma}_{FX,t+1}$.

4.2. *Time-varying conditional factor model*

Next, we describe a nonparametric approach to estimate a time-varying conditional factor model. Let $r_{i,t+1}$ be the excess return of currency portfolio i at time $t+1$, and $\sigma_{FX,t}$ is FX volatility. The excess return is represented by the following conditional factor model:

$$ret_{i,t+1} = \alpha_{i,t+1} + \gamma_{i,t+1}\sigma_{FX,t} + \epsilon_{i,t+1} \tag{13}$$

where $\alpha_{i,t+1}$ is the time-varying conditional alpha and $\gamma_{i,t+1}$ is the time-varying factor loading (beta) for portfolio i. The error term $\epsilon_{i,t+1}$ has conditional expectation $E[\epsilon_t \mid \sigma_{FX,t}, \gamma_{i,t+1}] = 0$ and conditional variance $E[\epsilon^2_{i,t+1} \mid \sigma_{FX,t}, \gamma_{i,t+1}] = \Omega_{t+1}$. Following Ang and Kristensen (2012), we introduce τ when estimating a kernel regression, and $\alpha_{i,\tau}$ and $\gamma_{i,\tau}$ at any point τ in the interval $1 \leq \tau \leq T$ are obtained by minimizing the following local kernel-weighted least-squared residuals:

$$[\hat{\alpha}_{i,\tau}, \hat{\gamma}_{i,\tau}] = \arg\min_{(\alpha,\gamma)} \sum_{t=1}^{T-1} K_{h_i T}(t-\tau)(r_{i,t+1} - \alpha_i - \gamma_i \sigma_{FX,t})^2 \tag{14}$$

where $K_{h_iT} = K(z/(h_iT))/(h_iT)$ with $K(\cdot)$ being a kernel with bandwidth $h_i > 0$ We choose the Gaussian kernel, which is widely used in the finance literature (see, e.g., Ang and Kristensen, 2012; Adrian et al., 2015). $\hat{\alpha}_{i,\tau}$ and $\hat{\gamma}_{i,\tau}$ are obtained by solving Equation (14). We need to choose bandwidths to solve Equation (14). Kristensen (2012), and Ang and Kristensen (2012) employ a "plug-in" method to select the bandwidths, since cross-validation procedures may provide extremely small bandwidths.[6]

5. Data

5.1. *Currency data*

Daily spot and one-month forward rates against the U.S. dollar were obtained from Datastream. Following Kroencke et al. (2014) and Bakshi and Panayotov (2013), we employ the G-10 currencies. They are the most liquid currencies and are widely used in currency investment strategies. Currency portfolios are rebalanced at the end of every month. The full time series span is from December 1983 to April 2017. To compute real exchange rates, the Consumer Price Index is obtained from OECD/Main Economic Indicators.

5.2. *U.S. and global macroeconomic data*

U.S. and global macroeconomic data series are used to construct empirical factor model. We employ 88 U.S. macroeconomic indicators, as in Ludvigson and Ng (2007). The groups of series included are: income, consumption, employment, production, housing starts, producer and consumer prices, interest rates, money supply, and stock markets. In addition to the U.S. data set, this study also employs global macroeconomic data series, and Filippou and Taylor (2017) address the idea that the global data are important for exchange rate markets. The global data series are obtained from G-10 countries and we employ 57 macroeconomic indicators: employment, production, producer and consumer prices, interest rates, foreign reserves, and stock markets.[7] The U.S. and the global data series are mainly

[6] See Kristensen (2012), and Ang and Kristensen (2012).

[7] We do not include trade balance data series since they cover relatively shorter periods compared with other global data series. When we include the trade balance data, they do not impact our results.

downloaded from the Federal Reserve Bank of St. Louis, and extend from January 1984 to September 2016.[8] We linearly interpolate some quarterly values to obtain data at the monthly frequency, as in Vissing-Jørgensen and Attanasio (2003). All data series are transformed based upon unit root tests and standardized to estimate factor models.

6. Empirical results

6.1. *Descriptive statistics*

We begin our empirical results section with summary statistics of each currency trade. Table 1 shows that average annualized excess return, annualized standard deviation, return skewness, return kurtosis, monthly maximum values, monthly minimum values and Sharpe ratios. An average annual excess return of the carry portfolio which goes long in two currencies and goes short in two currencies is 2.99%. The carry portfolio shows negative skewness, which is a typical characteristic of carry portfolios (e.g. Brunnermeier et al., 2009; Bakshi and Panayotov, 2013). In contrast, the good carry trade portfolio does not have negative skewness and the Sharpe ratio is higher than that of the corresponding carry portfolio (Bekaert and Panayotov, 2019).

6.2. *The risk-return relation estimated by the unconditional model*

Before estimating conditional models, we present unconditional results as a benchmark and motivation for our main approach. Realized volatility at time t is regressed onto the expected return at time $t+1$. Table 2 displays the parameter estimates for the unconditional model, and column (1) indicates that the estimated parameter for carry is negative and marginally statistically significant at the 10% level. This negative value of carry γ implies that additional risk is associated with lower return, irrespective of economic states, although the unconditional relationship is not strong in a statistical sense. In contract, the estimated carry α is statistically significant at the 5% level. The carry return is associated with a global business cycle, which means that past FX volatility is not sufficient to explain the

[8] As predicted FX volatility is used in Equation (12), currency portfolio returns extend by September 2016.

expected return (Bakshi and Panayotov, 2013; Ready et al., 2017; Byrne et al., 2019). Given that γ is not important for any other portfolios and R^2s are consistently low, the importance of economic states for risk-return trade-offs, and therefore γ is potentially washed out using an unconditional approach. Overall, the unconditional model results do not identify a risk-return trade-off in the foreign exchange market.

6.3. *Volatility estimation results*

In the previous section we identified a weak unconditional relationship between expected return and volatility. Given that this relationship may be contingent upon economic states, we now investigate this relationship using a conditional approach. First, we examine conditional volatility using the factor model in Equation (12). Table 3 presents parameter estimates for the factor model and column (1) uses only U.S. common factors. We adopt the general-to-specific approach and only retain statistically significant parameters. The common factors F_1 and F_5 are the main drivers explaining future FX volatility. Following Ludvigson and Ng (2007), we obtain marginal-R^2 to interpret these factors, and F_1 is strongly linked to output variables such as industrial production growth.[9] This is associated with the idea that industrial production captures business cycles (e.g. Lustig et al. 2014). Furthermore, F_5 is associated with money supply and commercial banks' assets. Both level and squared terms of F_1 and F_5 are statistically significant at least at the 5% level in Table 3.

We add lagged FX volatility in column (2) of Table 3, since Guo and Whitelaw (2006) report that lagged volatility is an important variable to predict future stock market volatility. We confirm the same result for FX volatility and the lagged FX volatility increases R^2 to 0.53. The empirical result also suggests that the lagged FX volatility drives out F_5, F_4^2, and F_5^2, while the real output factor F_1 remains statistically significant. This indicates that the U.S. real output is strongly linked to future FX volatility.

Next, global common factors are also included in the regression model. Column (3) in Table 3 implies that the global factors G_5, G_1^2, and G_5^2 are statistically significant at least at the 5% level. G_1 is strongly correlated with producer price indices and G_5 is the short-term interest rate factor. However,

[9] See the online Appendix Figure A4.

the incremental information to include the global factors is marginal, since a R^2 in column (3) is 0.40, which is almost similar to that of column (1).

Finally, both global factors and lagged FX volatility are included in column (4) of Table 3. We observe that the US real output factor and the lagged FX volatility are the main drivers to predict FX volatility. Furthermore, G_5, G_4^2, and G_5^2 have incremental information for the model, and G_4 is related to central banks' reserve variables. It is reasonable that global reserve and interest rate factors have different information from the U.S. real output factor. In summary, the U.S. factors, the global factors, and the past FX volatility predict future FX volatility.

FX volatility estimated by the factor model tracks realized FX volatility but with some advantages. Figure 1 compares the estimated and the realized FX volatilities. Interestingly, the realized volatility has clearer spikes than the estimated volatility, which is consistent with the notion that realized volatility contains relatively more noise than signal, with the factor model providing a smooth series which summarizes a large amount of information. We will use the fitted value of the final model in Table 3 column (4) for the next risk-return trade-off analysis. Although the R^2 of column (2) is slightly higher than that of column (4), while employing the latter model is more reasonable since it includes both U.S. and global information.

6.4. *The risk-return relation estimated by the factor model*

Given we have estimated future FX volatility, we now investigate risk-return relations using a factor model. Utilizing the estimated volatility, allows us to take investors' expectations into account. Furthermore, if risk-return trade-offs in foreign exchange rate markets are associated with business cycles, it is reasonable to employ global macroeconomic information. To extract information from a large numbers of macroeconomic variables, we adopt a factor model (e.g. Ludvigson and Ng, 2007). We repeat the same estimation reported in Table 2, while we replace realized FX volatility with estimated FX volatility.

Table 4 presents the risk-return relation between estimated FX volatility and expected FX returns. We find the strong negative relations for carry portfolios, and the risk-return parameters for carry and IMB are statistically significant. R^2s also increase by around 7%, which highlights the importance of the common component across macroeconomic measures as in Jurado (2015), since the R^2s are greater than those of Table 2. In summary, we observe that there is no systematic trade-off between conditional volatility and expected returns.

6.5. *Time-varying risk-return relation*

The negative relation between conditional volatility and the expected return on carry and global imbalance portfolios may be due to a lack of time variation of the parameters. Although we extract investors' information by adopting the factor model, it may not be sufficient to reflect changes in economic states. Indeed, relations between conditional volatility and expected returns vary over time in the U.S. and European stock markets (e.g. Rossi and Timmermann, 2010; Ghysels et al., 2014; Aslanidis et al., 2016). This study employs the time-varying conditional factor model proposed by Ang and Kristensen et al. (2012), which does not impose any specifications on conditioning variables and parameters, and allows continuous changes in parameters.

Figure 2 presents time-varying risk-return parameters with 90% confidence intervals. We adopt the same model in Table 4 and the risk-return parameter of carry trade is negative whereas the magnitude varies over time. It is close to zero around the years 2000 and 2012, while there are troughs around 1997 and 2006.[10] This means that when the carry trade provides a higher return, the parameter tends to be negative. Interestingly, both the risk-return parameters of value and momentum portfolios exhibit wider fluctuations and flip signs. This could be a helpful explanation as to why we do not observe significant relations between conditional volatility and expected returns in Table 4. The parameter values of the momentum portfolios reach 0.2 and those of the value portfolios attain 0.4, which are smaller than results reported by the stock market literature, but they are still meaningful because some studies do not find theoretically consistent signs (e.g. Glosten et al., 1993). In contrast, the risk-return parameters of good carry, AFD, IMB, and ΔFXC portfolios illustrate more stable changes since their bandwidths derived by Ang and Kristensen's (2012) method are larger than those of the other portfolios.

Our empirical results furthermore suggest that positive average returns of the momentum and the

[10] We also estimate the time-varying relations with realized FX volatility in Online Appendix. The impact becomes weaker than that of the estimated FX volatility model.

value strategies are explained by the standard risk-return framework. These parameters increase in particular during the global financial crisis, which suggests that investors require higher returns for investing in currency during a crisis. Guiso et al. (2018) investigate investors' surveys which were conducted in 2007 and 2009. Investors were asked questions related to a subjective risk belief and a certainty equivalent value. Guiso et al. (2018) observe that investors' risk aversion increased in 2009 and most investors chose more conservative risk-return combinations at that time.

Our main findings are also related to the currency momentum literature. Menkhoff et al. (2012b) indicate that it is difficult to explain average positive returns of the currency momentum strategies based upon the standard financial factors. Our empirical findings reveal that the time variation of the risk-return parameters plays an important role. Overall, we find that the signs of parameters on the momentum and the value portfolios are consistent with the risk-return story.

7. Further analysis

The results obtained in the previous section demonstrate the importance of introducing time variation. In this section, we investigate the further analysis of our findings. First, we use a rolling regression approach that is widely employed to obtain time-varying coefficients. Second, we formally test whether time-varying risk-return relations are associated with business cycles.

7.1. *Rolling regression approach*

Given we present formal statistical evidence of time-varying relations between conditional volatility and we use a data intensive non-parametric approach, and hence we may have insufficient data to successfully to draw confidence intervals. We employ a more conservative rolling regression approach to examine time variations (e.g. Lustig et al., 2011). We choose a rolling window size as an optimal bandwidth employed in the previous section.

Figure 3 demonstrates the time-varying relations obtained by the rolling regressions. Our main findings remain the same and the risk–return parameters on the momentum and the value portfolios flip signs. More importantly, both parameters increase in the financial crisis and these confidence intervals are above zero. Derived optimal bandwidths of good carry, AFD, and ΔFXC portfolios are large, and the estimation periods are short. In addition, we find that the zero axis is within error bands more frequently for the rolling regression, since the nonparametric regression fits local data and has more flexible functional form.[11]

7.2. *Characterizing changes in risk-return trade-offs*

Having found that the risk-return trade-off varies over time, we explore whether these changes are driven by business cycles. We regress a change in the risk-return parameter $\gamma_{i,t}$ in Equation (13) for each result onto changes in U.S. and global industrial production growths and those in changes in U.S. and global short-term rate. We employ the global industrial production growth and the global short-term rate as first principal components of G10 countries excluding U.S. data. Then, following Lustig et al. (2014) and Bekaert and Panayotov (2019), we extract a residual by regressing the U.S. variable onto the global variable.

The change in $\gamma_{i,t}$ of the momentum portfolio is driven by U.S. industrial production growth and the global short-term rate. Weak business conditions are proxied by low industrial production growth and a high interest rate (Ang and Kristensen, 2012; Lustig et al., 2014). Results in Table 5 indicate that the momentum portfolio is consistent with the risk story. U.S. industrial production growth, ΔIP_{us}, and the global short-term rate, Δi_{world}, are statistically significant at the 1% level. Also the estimated coefficient in Table 5 on ΔIP_{us} has a negative sign and Δi_{world} has a positive sign. This is consistent with the momentum risk-return relationship being counter-cyclical: risk requires greater compensation in a downturn, than would otherwise be the case. For the value portfolio, U.S. and global short rates and U.S. industrial production, are statistically significant at least at the 5% level. The sign on the U.S. short rate is counter cyclical, while those on the other two are pro-cyclical. Finally, the result of the ΔFXC portfolio is similar to that of the momentum portfolio, while the change in $\gamma_{i,t}$ for the ΔFXC portfolio is slow, we should be cautious to conclude that the risk-return trade-off hold for the ΔFXC

[11] For an econometric critique of rolling windows in conditional asset pricing models see Gagliardini et al. (2016).

portfolio.

8. Conclusion

To summarise our study, we theoretically motivate and empirically explore risk-return relations between conditional volatility and expected returns on currency portfolios. This allows us to uncover time-varying risk-return relationships in the foreign exchange market. Currency carry portfolios have similar characteristics to stock markets, as pointed out by Dobrynskaya (2014) and Lettau et al. (2014), while currency momentum and value portfolios are regarded as having more specific characteristics. Furthermore, we explore several new currency portfolios such as dollar carry trade (Lustig et al. 2014), global imbalance (Della Corte et al. 2016), good carry trade (Bekaert and Panayotov, 2019), and foreign exchange rate correlations (Mueller et al. 2017).

We introduce a time-varying relation in our analysis of the FX market, since it is frequently considered to be a key characteristic in the stock market (Whitelaw, 2000). We find that the risk-return trade-offs on the momentum, and value portfolios vary over time. The parameters on the momentum and the value portfolios increase in the financial crisis, which suggests that average high returns on them are explained by the risk-return story. In particular, the time variation of the momentum portfolio is linked to business cycles. We also observe that utilising a large number of data set can reflect investors' expectation. The factor model approach provides stronger results than the other approach employing realized volatility. This is potentially because the factor can uncover a stronger signal of risks, and underlying economic states, that impact the Foreign Exchange market, and their time-varying relationship to returns.

ΔFXC	2.65	8.36	-0.25	4.53	7.09	10.65	0.32

Notes: This table reports annualized mean, annualized standard deviations, skewness, kurtosis, maximum, minimum, and the Sharpe ratio of excess returns of currency portfolios. We employ seven currency portfolios: carry, momentum, value, good carry (good, Bekaert and Panayotov, 2019), Average Forward Discount (AFD, Lustig et al., 2014), global imbalance (IMB, Della Corte et al., 2016), and global correlation risk (ΔFXC, Mueller et al., 2017). Good carry portfolio includes three currency pairs. The sample period is January 1984 and September 2016.

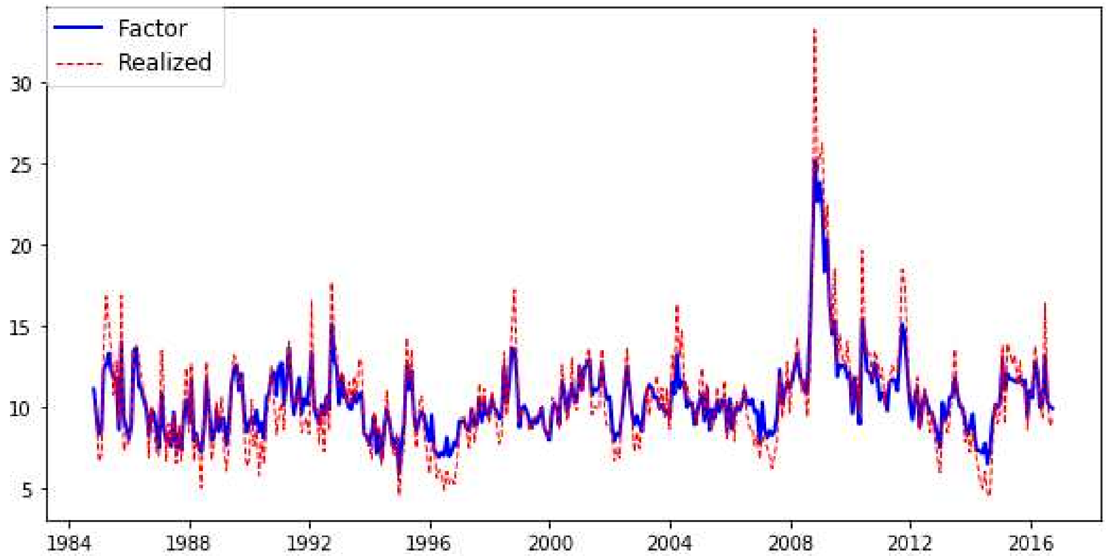
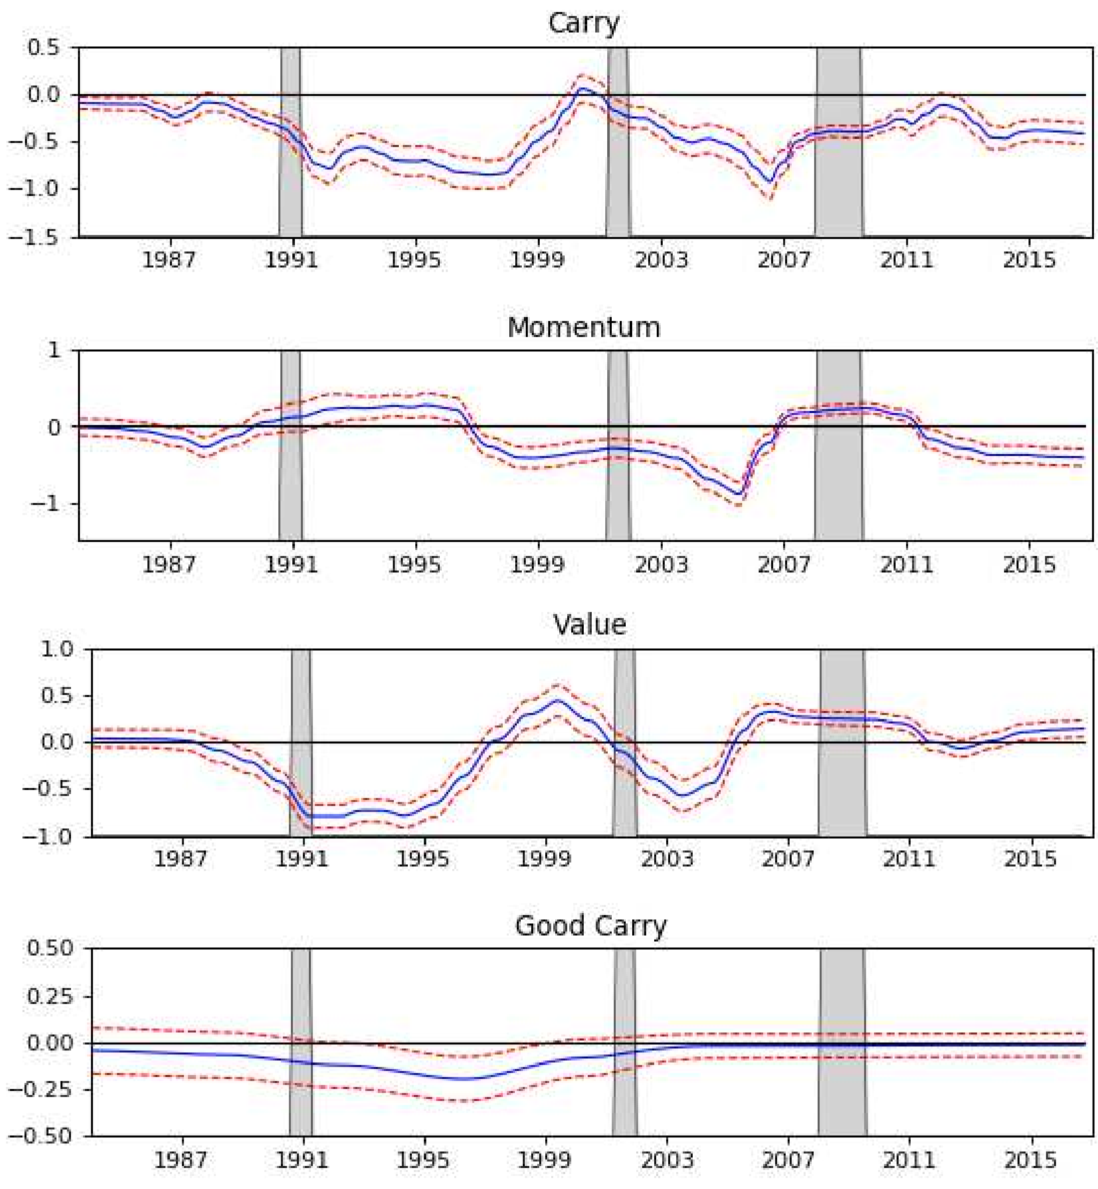
Notes: This table presents the results of the time-varying $\gamma_{i,t}$ on U.S. and global short rates, and U.S. and global industrial production as: $\gamma_{i,t} = a_i + b_1 \Delta i_{us,t} + b_2 \Delta i_{world,t} + b_3 \Delta IP_{us,t} + b_4 \Delta IP_{world,t} + e_{i,t}$. i_{world} and IP_{world} are residuals by regressing the U.S. variables onto the global variables which obtained by first principal components. We employ seven currency portfolios: carry, momentum, value, good carry (good, Bekaert and Panayotov, 2019), Average Forward Discount (AFD, Lustig et al., 2014), global imbalance (IMB, Della Corte et al., 2016), and global correlation risk (ΔFXC, Mueller et al., 2017). Good carry portfolio includes three currency pairs. The standard errors are reported in parentheses and obtained by the Newey and West (1987) procedure with optimal lag selection according to Andrews (1991). The adjusted R^2 is also reported. *,**, and *** indicate significance at the 10%, 5% and 1% levels, respectively. The sample period is between January 1984 and September 2016.

Figure 1. Realized and factor volatility



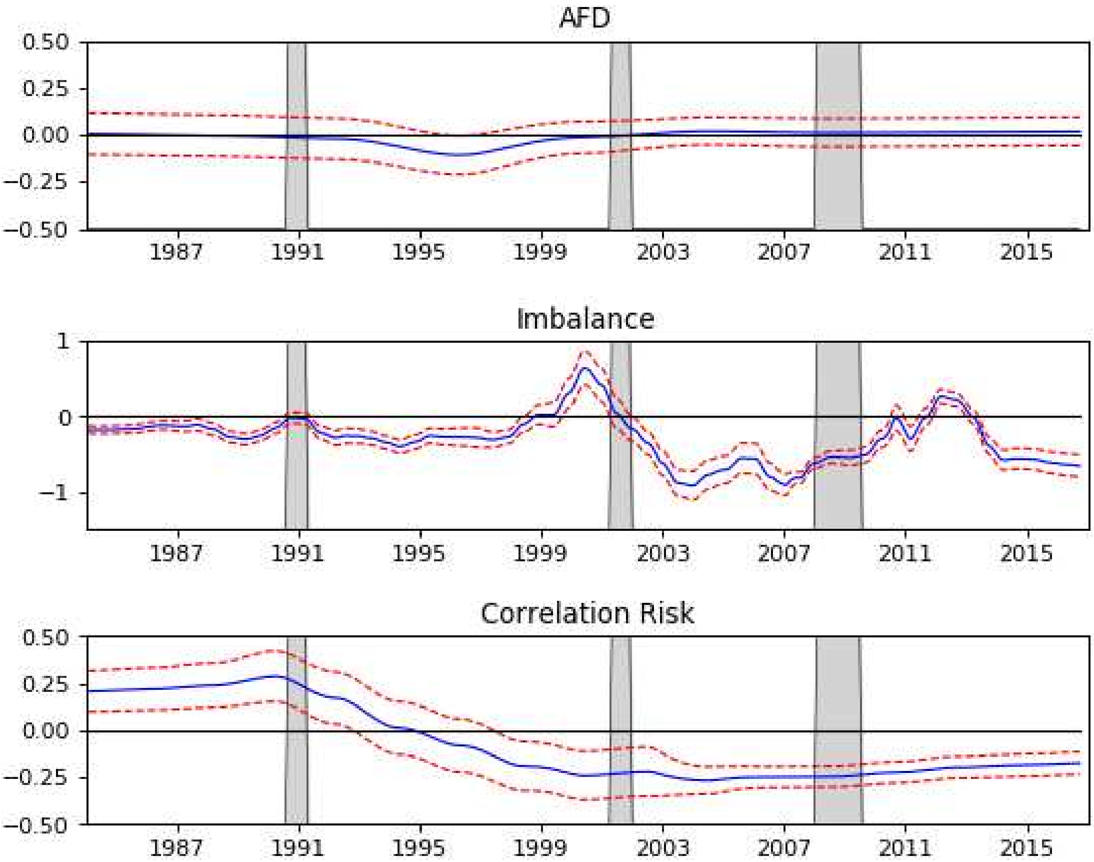
Notes: This figure presents realized and factor model volatility. The realized global FX volatility is calculted as: $\sigma_{FX,t} = \frac{1}{T_t}\sum_{d=1}^{T_t}\sigma_{FX,d}$ where $\sigma_{FX,d}$ is the daily global FX volatility and T_t is the total number of trading days in month t. The factor model volatility is estimated as: $\sigma_{FX,t+1} = \phi f_t + e_{t+1}$ where f_t is the common factors extracted from U.S. and global macroeconomic indicators. The sample period is between January 1984 and September 2016.

Figure 2. Time-varying trade-off between volatility and expected return: Kernel estimation



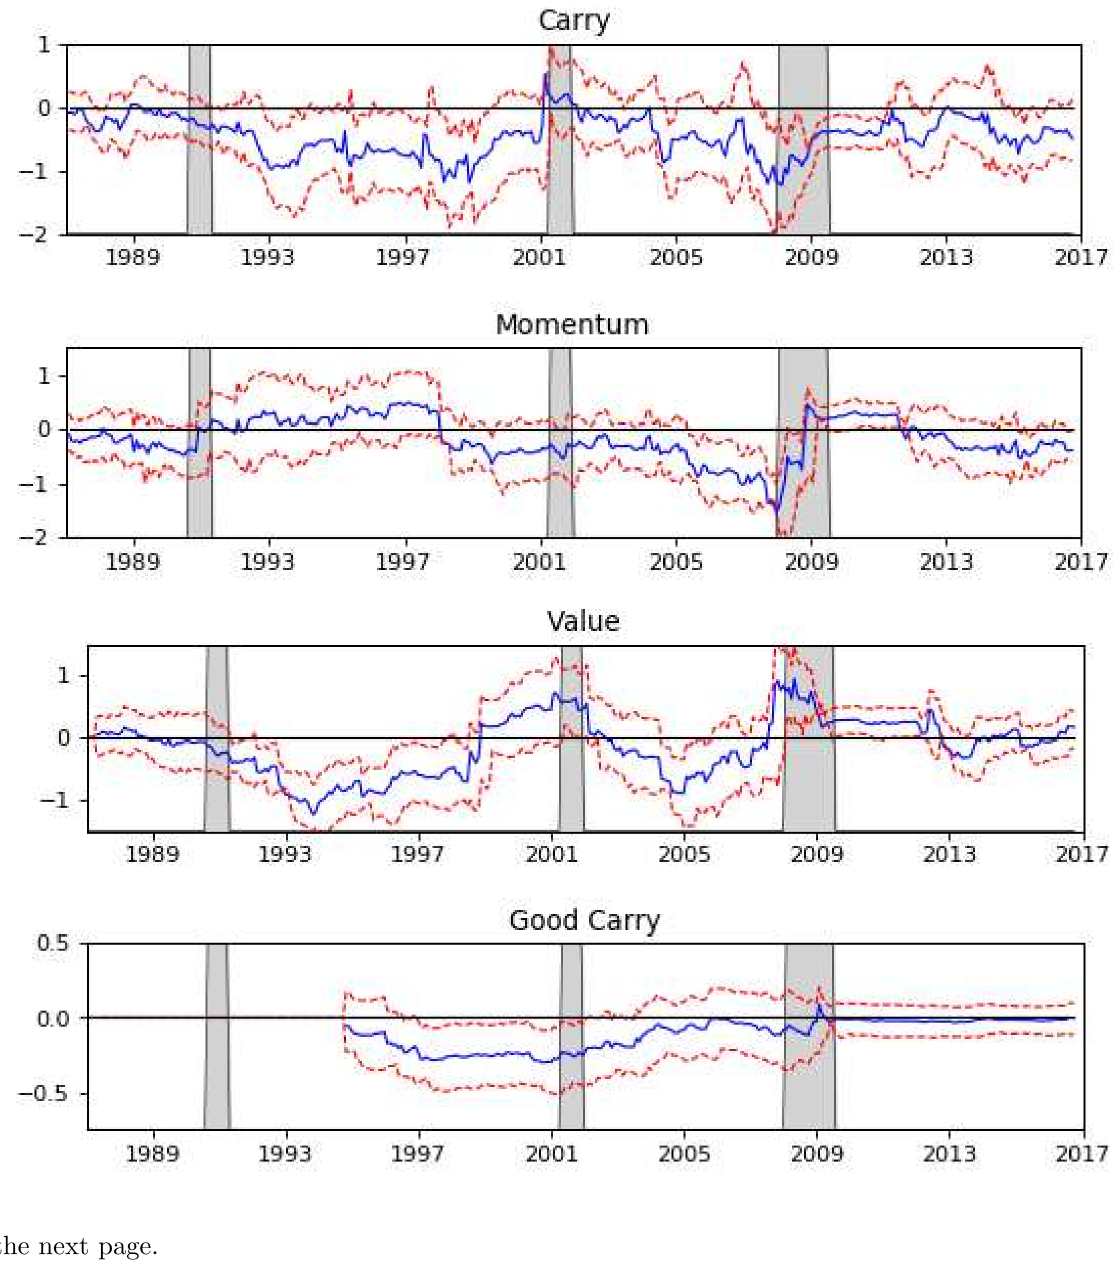
Notes: See the next page

Figure 2. continued



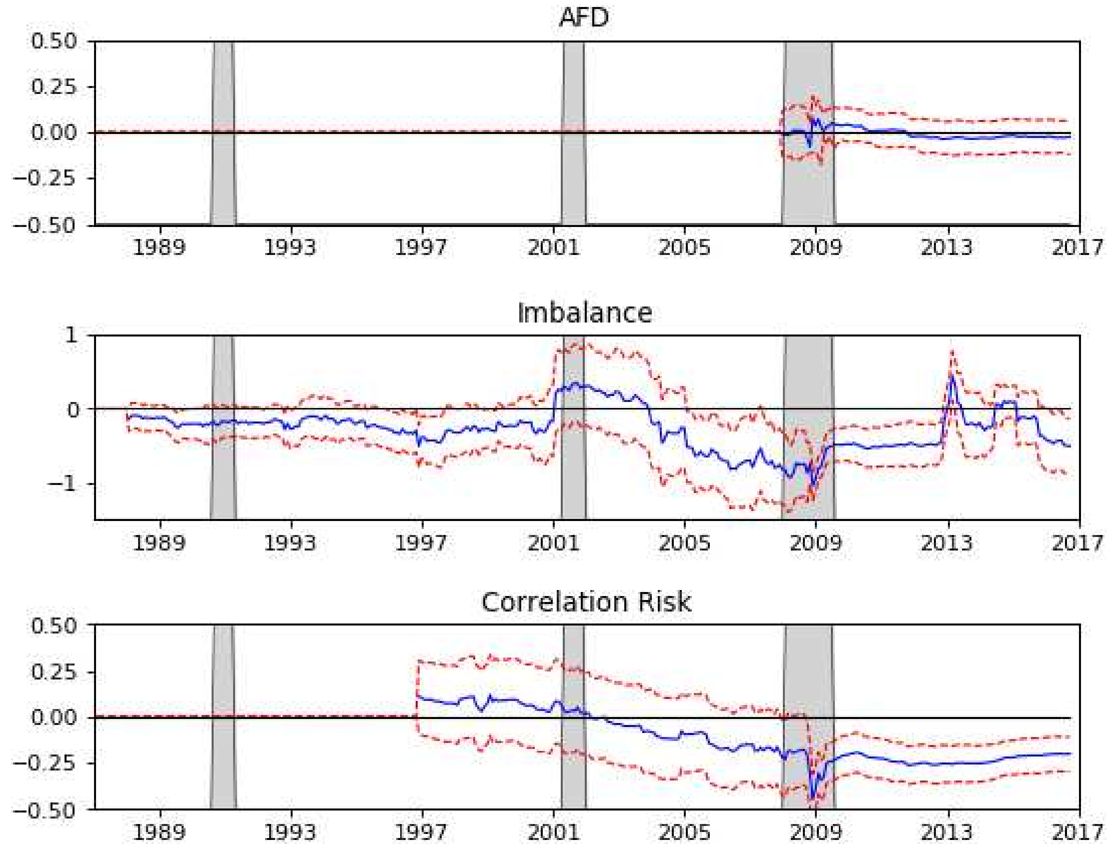
Notes:This figure provides plots of the estimated parameters with 90% confidence intervals. Ang and Kristensen (2012) estimation method is employed and predicted global FX volatility is obtained by the factor model. The confidence intervals are estimated based upon the standard errors derived by Ang and Kristensen (2012). We employ seven currency portfolios: carry, momentum, value, good carry (Bekaert and Panayotov, 2019), Average Forward Discount (AFD, Lustig et al., 2014), global imbalance (IMB, Della Corte et al., 2016), and global correlation risk (ΔFXC, Mueller et al., 2017). Good carry portfolio includes three currency pairs. The shaded regions are NBER recessions.

Figure 3. Time-varying trade-off between volatility and expected return: Rolling regression



Notes: See the next page.

Figure 3. continued



Notes:This figure provides plots of the estimated parameters with 90% confidence intervals. A rolling regression approach is employed and predicted global FX volatility is obtained by the factor model The rolling window size corresponds to the size of bandwidth used by the kernel estimation. We employ seven currency portfolios: carry, momentum, value, good carry (Bekaert and Panayotov, 2019), Average Forward Discount (AFD, Lustig et al., 2014), global imbalance (IMB, Della Corte et al., 2016), and global correlation risk (ΔFXC, Mueller et al.,2017). The shaded regions are NBER recessions.

The Conditional Risk and Return Trade-Off on Currency Portfolios

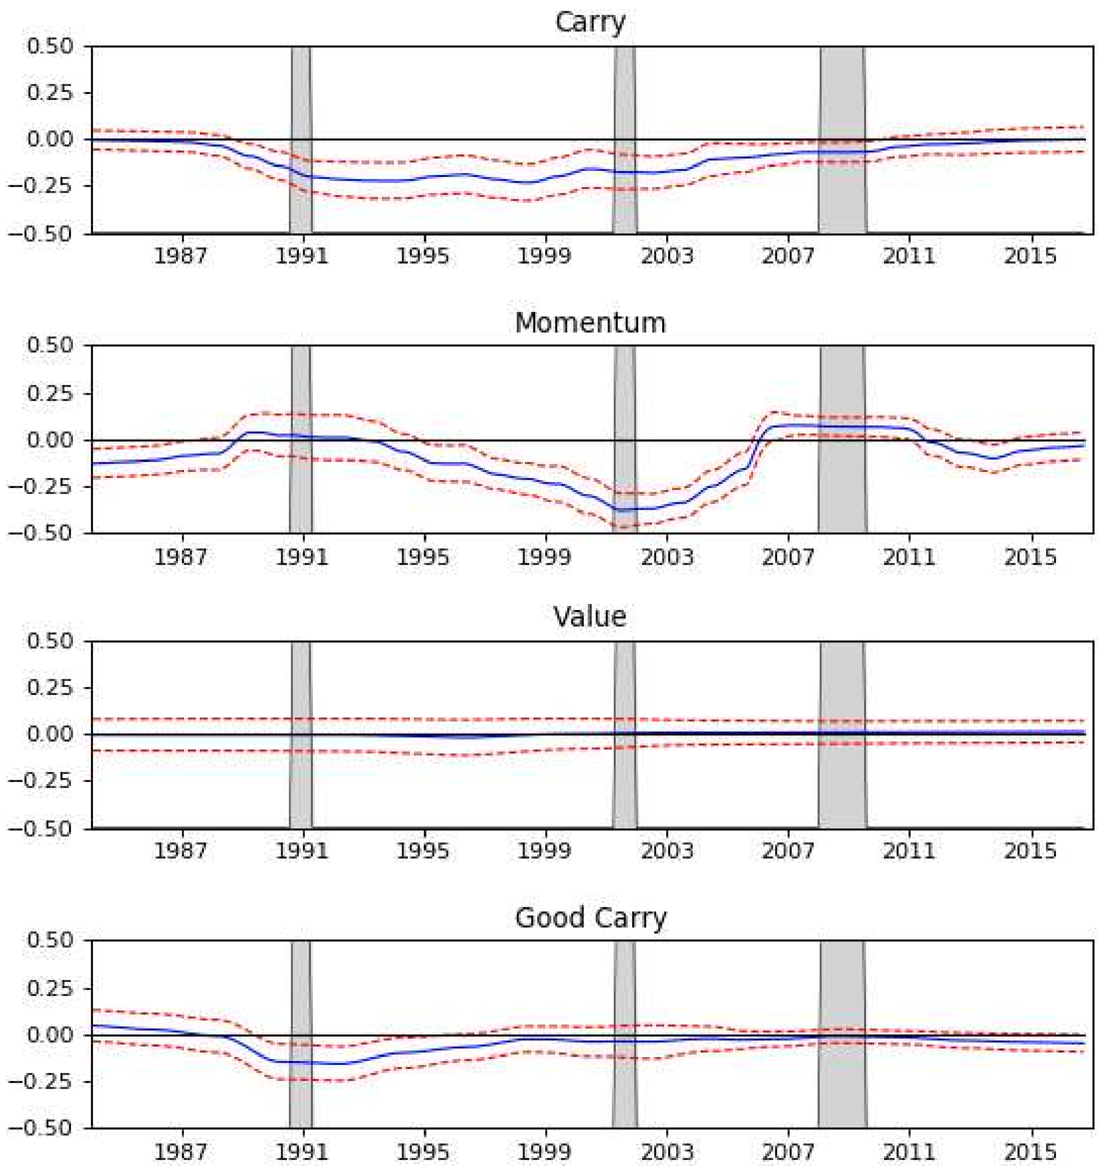
Joseph P. Byrne and Ryuta Sakemoto

7th April 2020

Online Supplement, Not for Publication

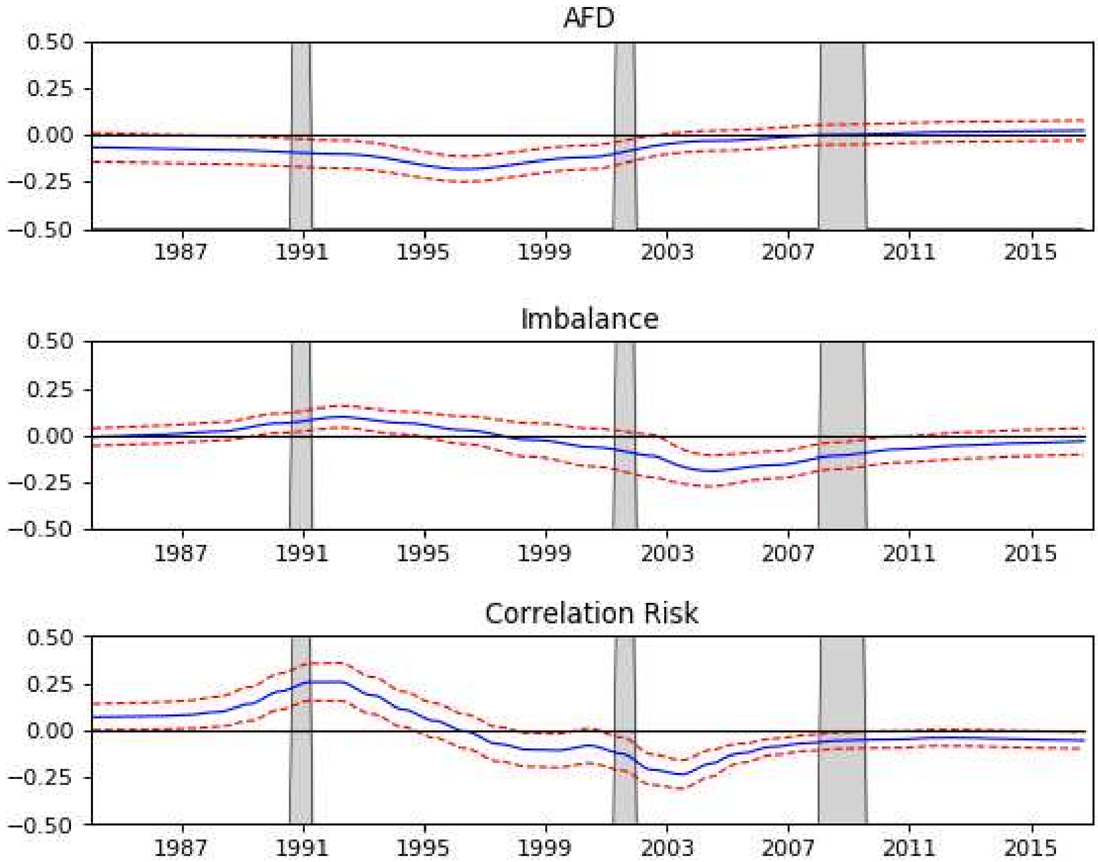
This material provides additional results which are not reported in the main text. These include Figure A1 Conditional trade-off between realized volatility and return, Figure A2 Rolling regression trade-off between realized volatility and return, Figure A3 Conditional trade-off between volatility and larger number of currencies and Figure A4-A9 marginal R^2 from empirical factor model. Table A1 is bandwidth estimation. Table A2-A4 provides data definition.

Figure A1. Time-varying trade-off between volatility and expected return: Realized volatility



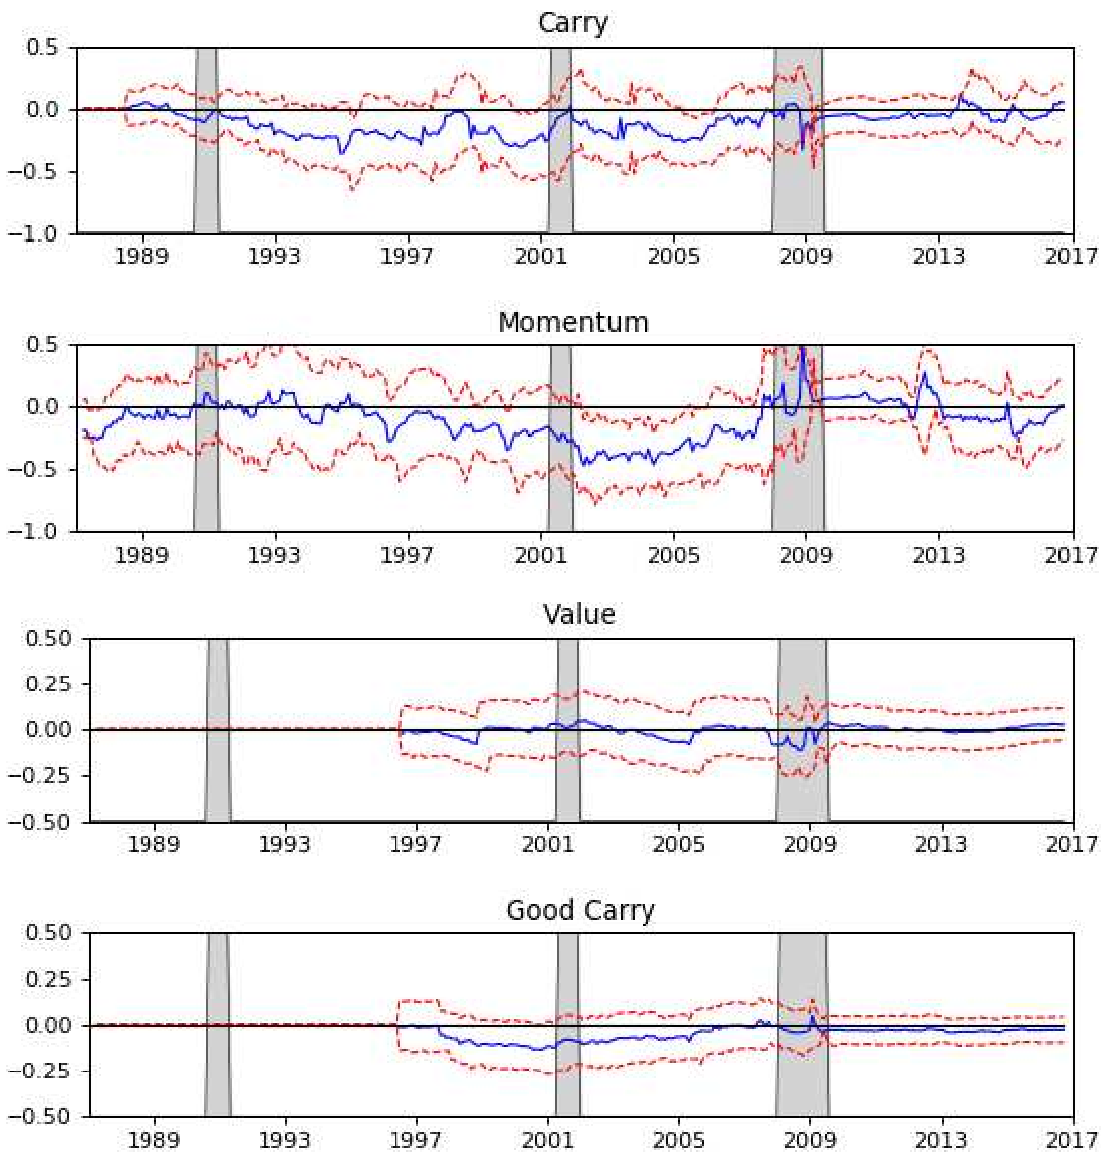
Notes: See the next page

Figure A1. continued



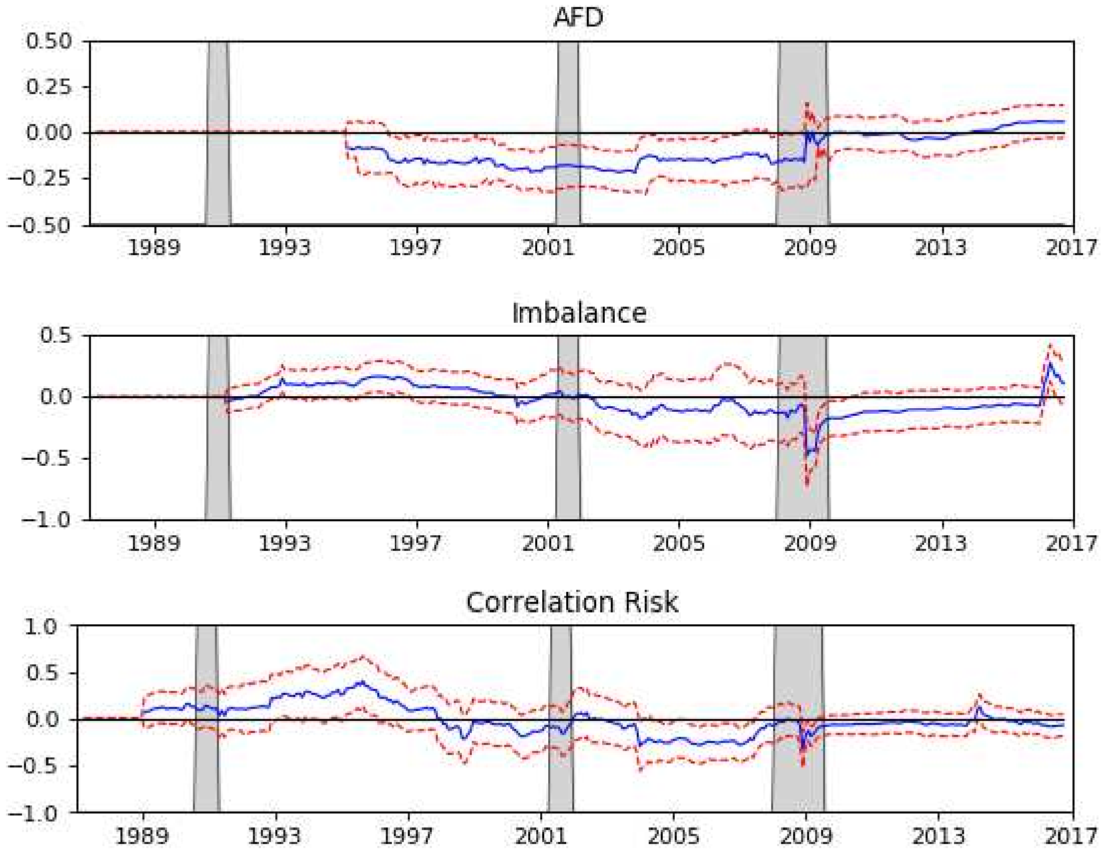
Notes:This figure provides plots of the estimated parameters with 90% confidence intervals. Ang and Kristensen (2012) estimation method is employed and predicted global FX volatility is realized volatility. The confidence intervals are estimated based upon the standard errors derived by Ang and Kristensen (2012). We employ seven currency portfolios: carry, momentum, value, good carry (Bekaert and Panayotov, 2019), Average Forward Discount (AFD, Lustig et al., 2014), global imbalance (IMB, Della Corte et al., 2016), and global correlation risk (ΔFXC, Mueller et al., 2017). The shaded regions are NBER recessions.

Figure A2. Time-varying trade-off between volatility and expected return: Realized volatility



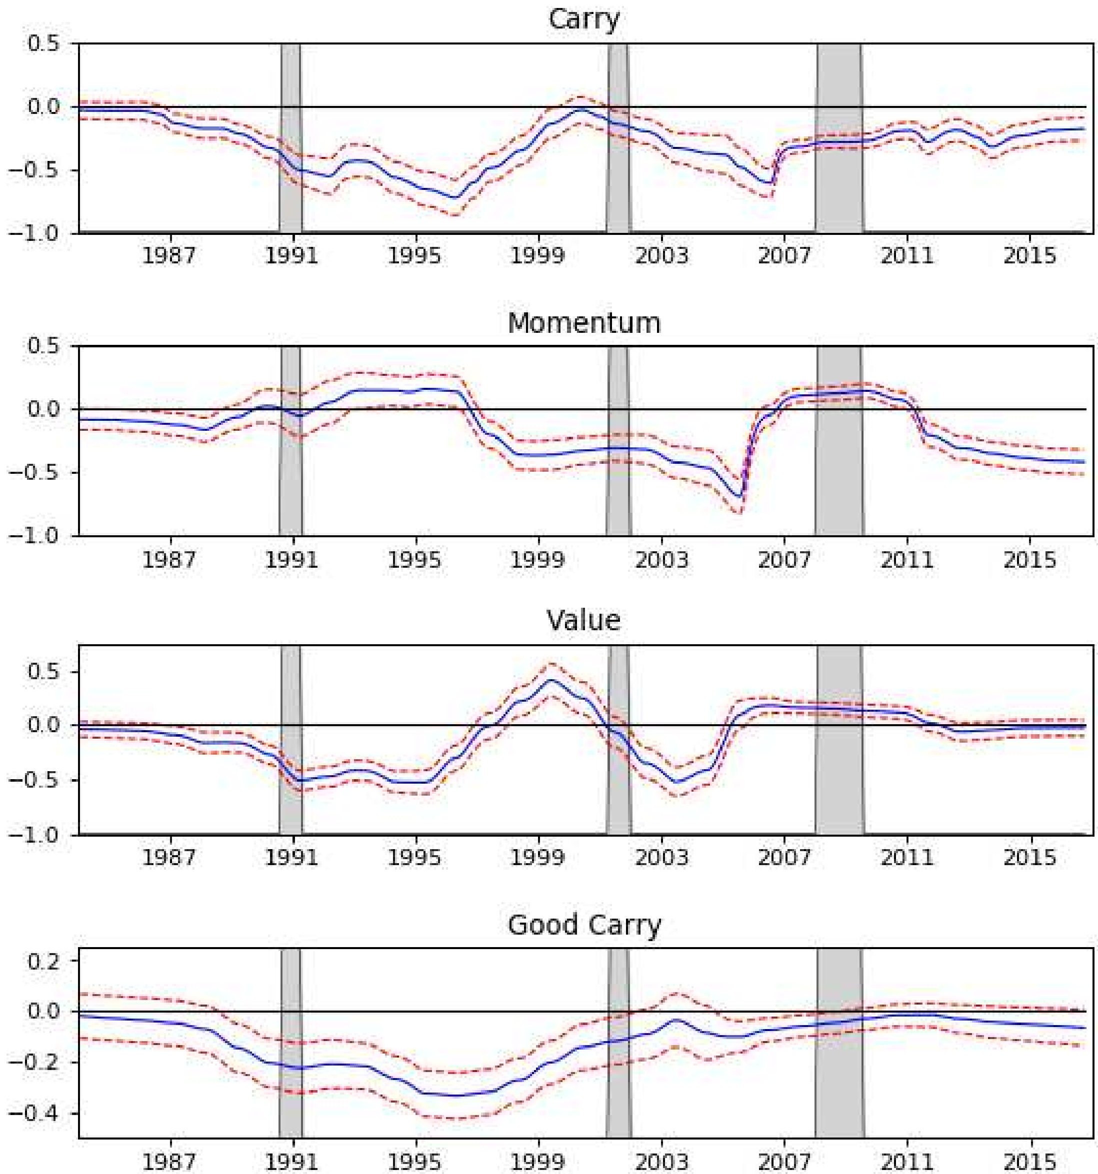
Notes: See the next page.

Figure A2. continued



Notes:This figure provides plots of the estimated parameters with 90% confidence intervals. A rolling regression approach is employed and predicted global FX volatility is realized volatility. The rolling window size corresponds to the size of bandwidth used by the kernel estimation. We employ seven currency portfolios: carry, momentum, value, good carry (Bekaert and Panayotov, 2019), Average Forward Discount (AFD, Lustig et al., 2014), global imbalance (IMB, Della Corte et al., 2016), and global correlation risk (ΔFXC, Mueller et al., 2017). The shaded regions are NBER recessions.

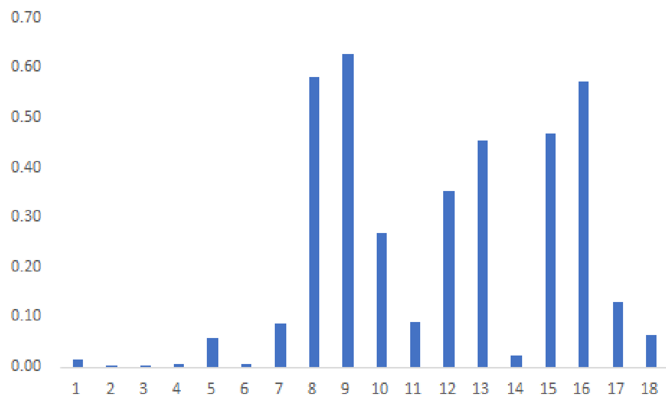
Figure A3. Time-varying trade-off between volatility and expected return: Six currencies



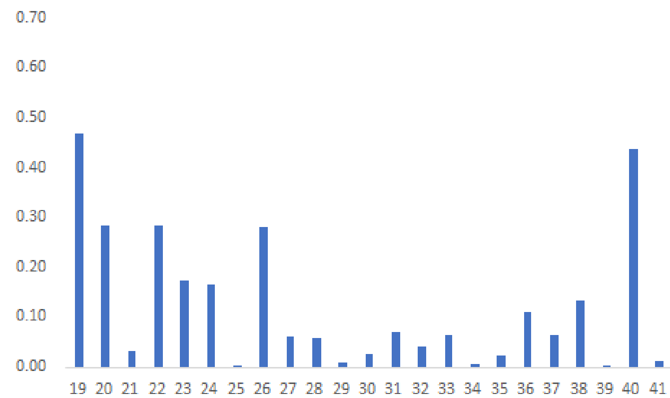
Notes: Notes:This figure provides plots of the estimated parameters with 90% confidence intervals. Three currencies go long and three currencies go short. Ang and Kristensen (2012) estimation method is employed and predicted global FX volatility is obtained by the factor model. The confidence intervals are estimated based upon the standard errors derived by Ang and Kristensen (2012). We employ seven currency portfolios: carry, momentum, value, good carry (Bekaert and Panayotov, 2019),

Figure A4. Marginal R^2 for F_1

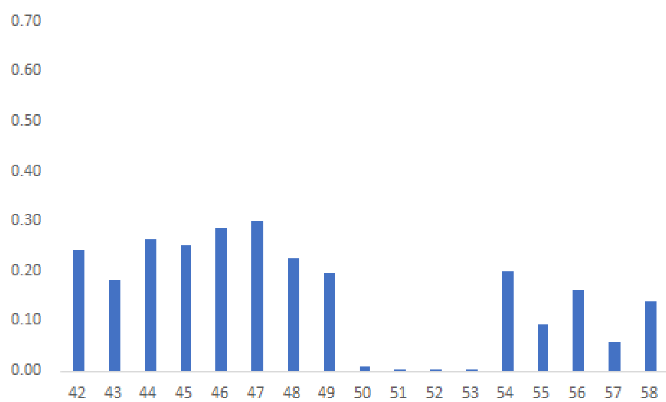
Money, production, income, and consumption



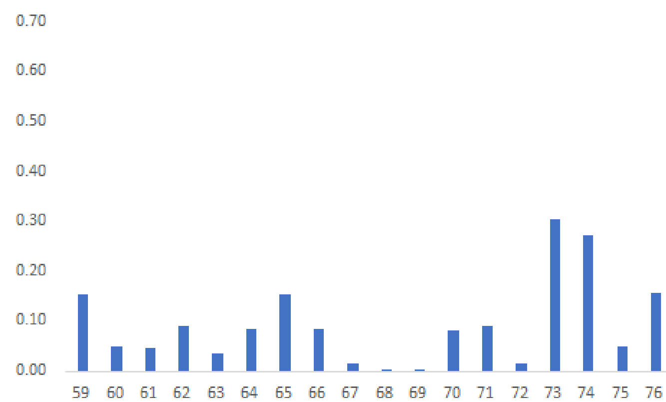
Employment, hours, and prices



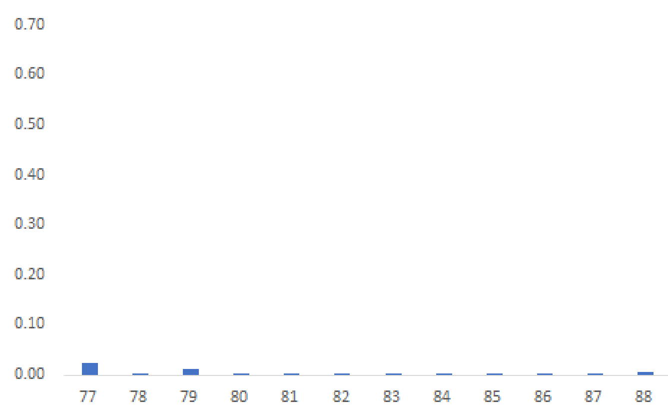
Interest rate, exchange rate, and expenditure



Housing

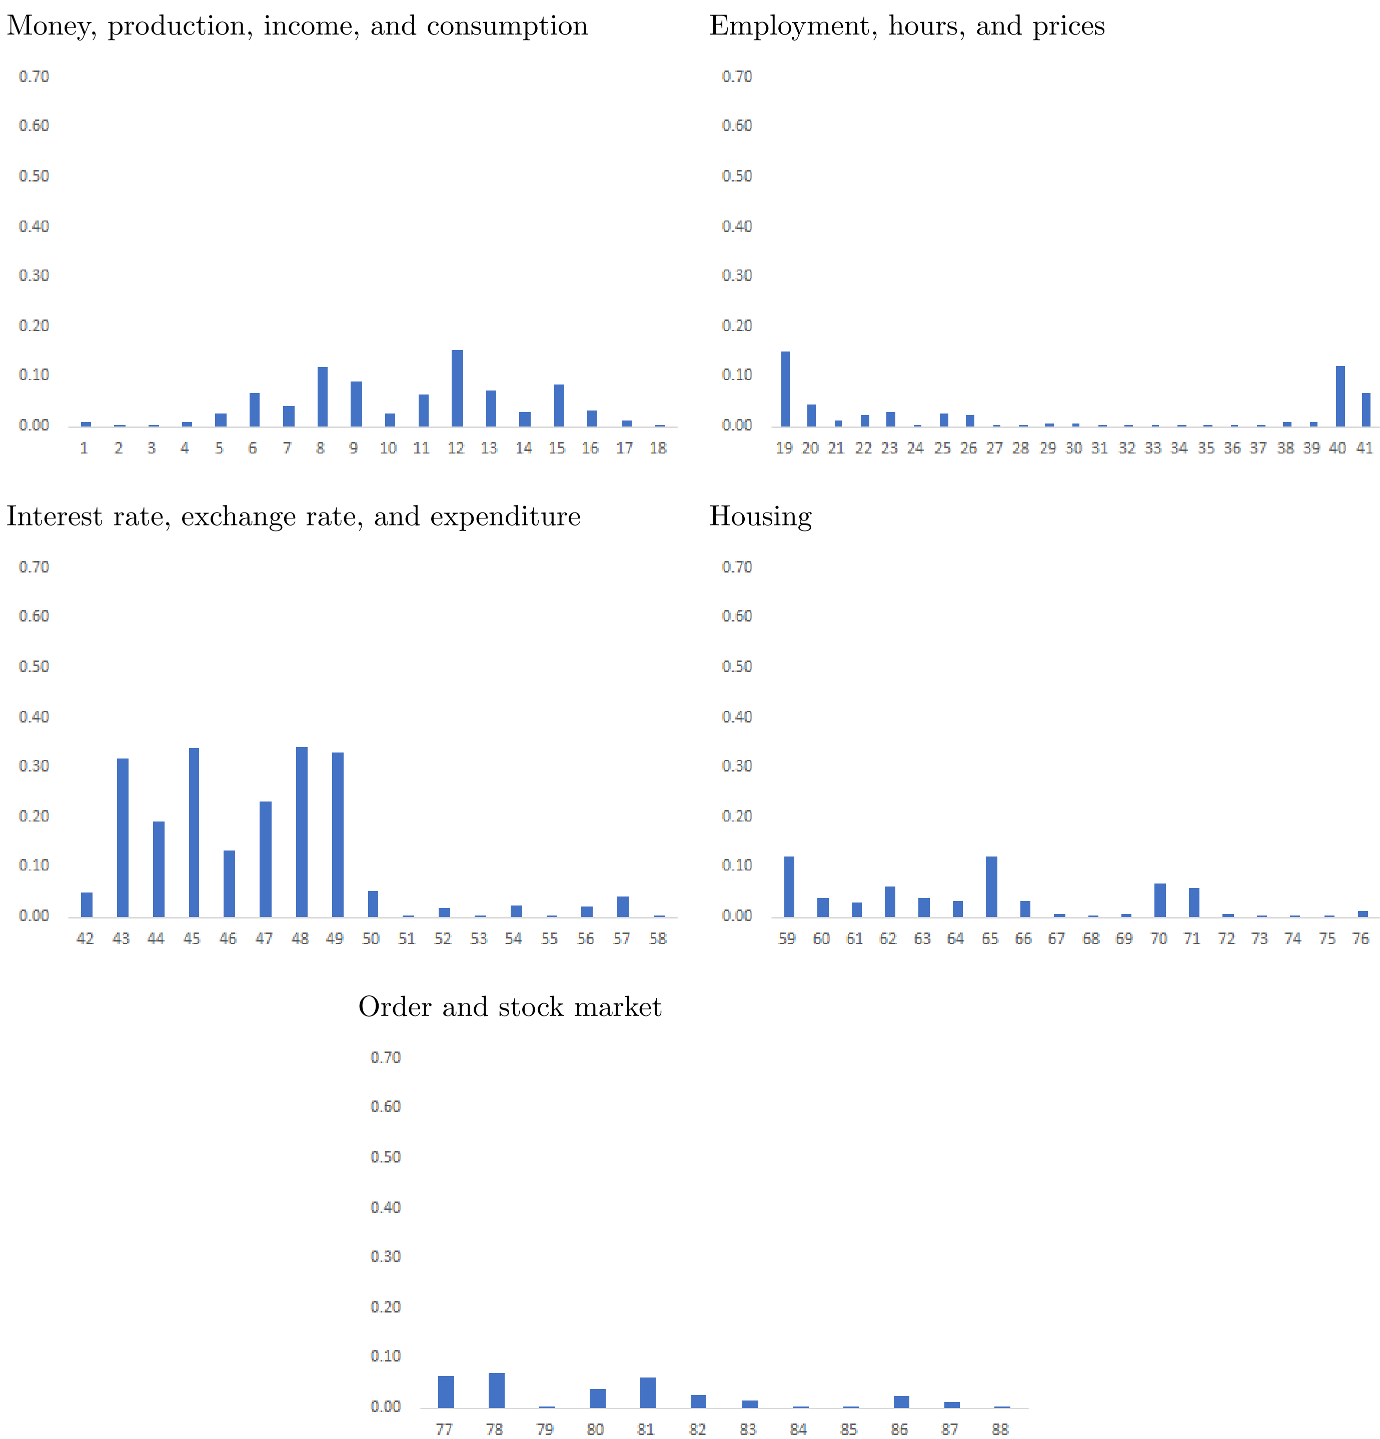


Order and stock market



Notes: This figure present the R-square from regressing the U.S. macroeconomic series number given on the x-axis onto the estimated factor named in the heading. See the Table A3 for a description of the numbered series.

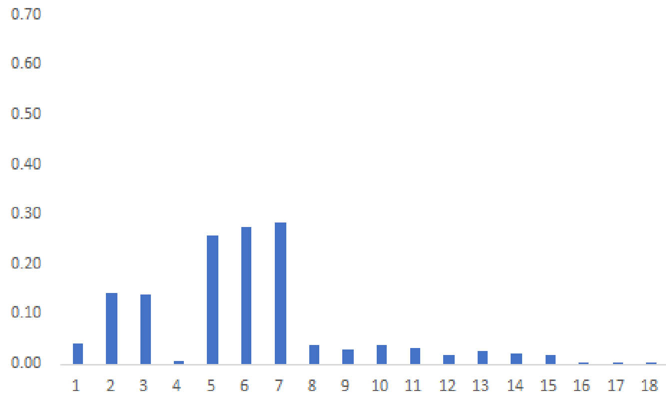
Figure A5. Marginal R^2 for F_4



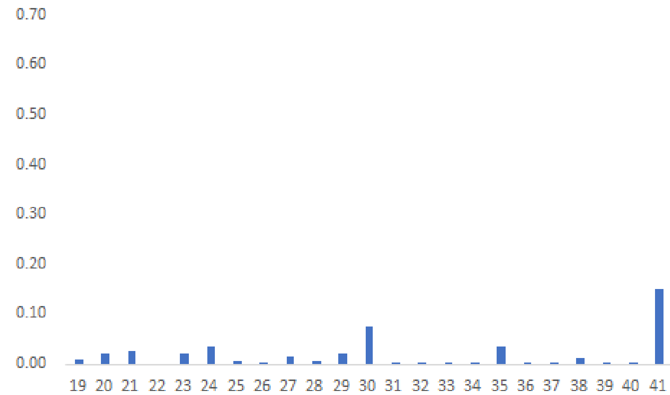
Notes: This figure present the R-square from regressing the U.S. macroeconomic series number given on the x-axis onto the estimated factor named in the heading. See the Table A3 for a description of the numbered series.

Figure A6. Marginal R^2 for F_5

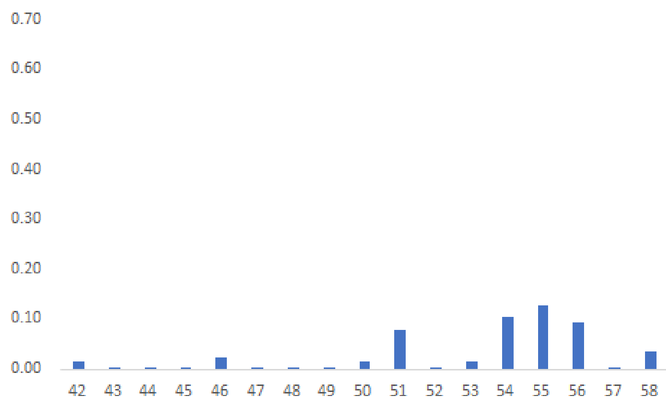
Money, production, income, and consumption



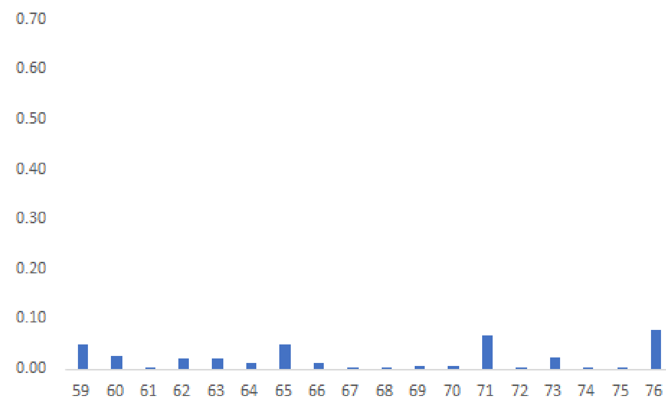
Employment, hours, and prices



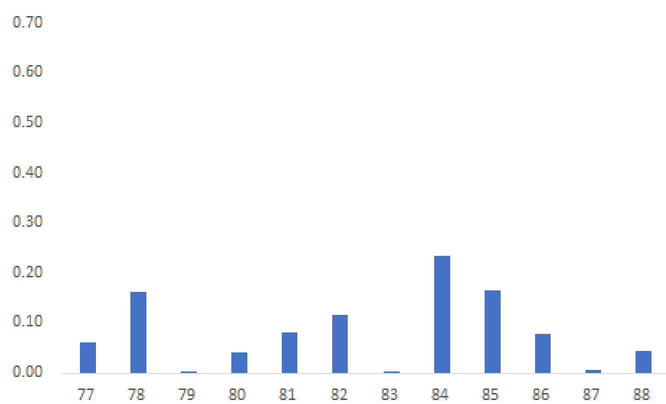
Interest rate, exchange rate, and expenditure



Housing



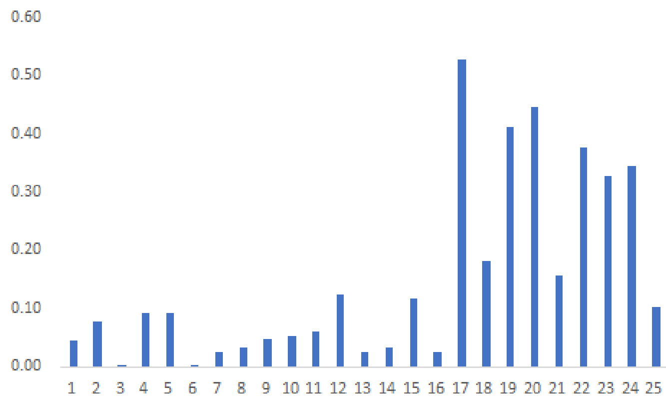
Order and stock market



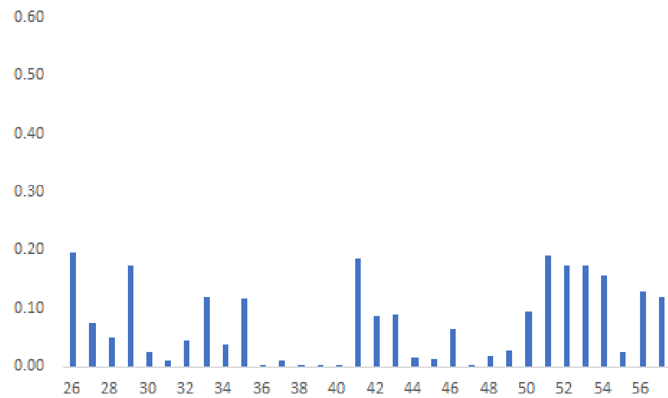
Notes: This figure present the R-square from regressing the U.S. macroeconomic series number given on the x-axis onto the estimated factor named in the heading. See the Table A3 for a description of the numbered series.

Figure A7. Marginal R^2 for G_1

Production, employment, and PPI



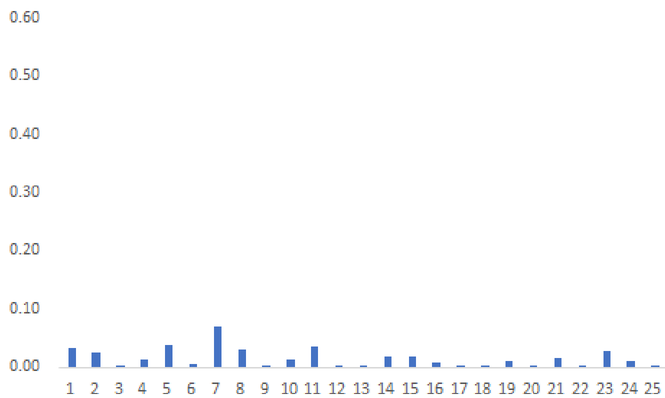
CPI, interest rate, reserves, and stock market



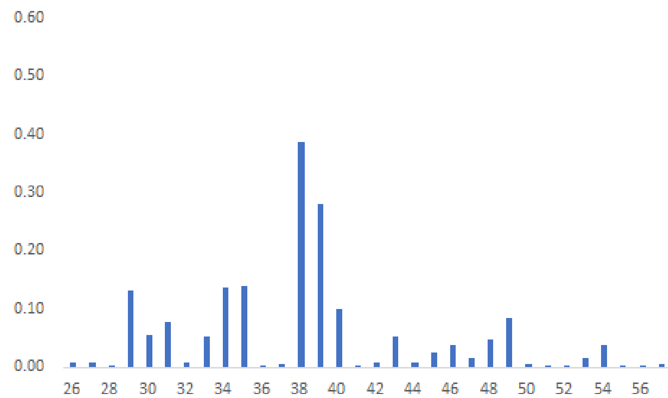
Notes: This figure present the R-square from regressing the global macroeconomic series number given on the x-axis onto the estimated factor named in the heading. See the Table A4 for a description of the numbered series.

Figure A7. Marginal R^2 for G_4

Production, employment, and PPI



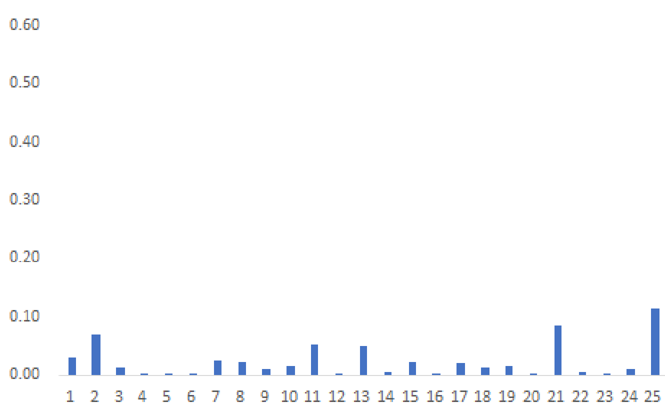
CPI, interest rate, reserves, and stock market



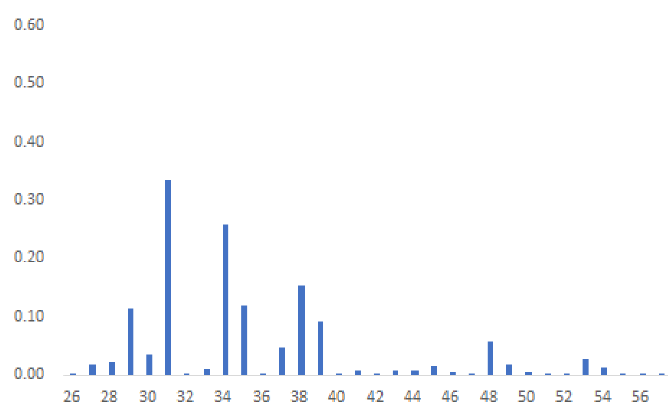
Notes: This figure present the R-square from regressing the global macroeconomic series number given on the x-axis onto the estimated factor named in the heading. See the Table A4 for a description of the numbered series.

Figure A8. Marginal R^2 for G_5

Production, employment, and PPI



CPI, interest rate, reserves, and stock market



Notes: This figure present the R-square from regressing the global macroeconomic series number given on the x-axis onto the estimated factor named in the heading. See the Table A4 for a description of the numbered series.

Table A1 Estimates of Bandwidths

	carry	mom	value	good	AFD	IMB	ΔFXC
Realized Volatility	107.1	75.94	299.35	289.7	260.7	172.5	119.5
Factor Model	53.7	66.3	78.3	257.2	115.0	47.7	154.2

Notes: This table reports estimates of bandwidths and the values are reported as monthly equivalent units. We employ the method proposed by Ang and Kristensen (2012). We employ seven currency portfolios: carry, momentum, value, good carry (Bekaert and Panayotov, 2019), Average Forward Discount (AFD,Lustig et al., 2014), global imbalance (IMB, Della Corte et al.,2017), and global correlation risk (ΔFXC, Mueller et al.,2017).
